Introduction

Nicotine, a principal pyridine alkaline in tobacco plants, is notorious for its significant contribution to tobacco addiction. However, nicotine is very toxic to humans because it is easily absorbed in the body; its hydrophilic nature contributes to the absorption in the body. Moreover, large quantities of tobacco wastes containing high concentration of nicotine are produced during tobacco manufacturing process. These wastes have been classified as “toxic and hazardous wastes” by European Union Regulations [2]. In addition, the American Medical Association has issued a public strategy strengthening the forcible reduction of nicotine level in tobacco [3]. As an environment-friendly treatment, microbial degradation of nicotine has been considered as a promising method due to its low cost and high efficiency.

In recent years, studies elucidating the mechanisms underlying nicotine degradation by microorganisms have drawn considerable attention. Previously, several bacteria including *Arthrobacter* species [4], *Pseudomonas* species [5–8], *Ochrobactrum intermedium* [9], *Rhodococcus* species [10], *Enofer* species [11], and *Agrobacterium* species [12] have been reported to degrade nicotine. There are three pathways for nicotine metabolism: (1) the methyl pathway, used by some fungi such as *Pellicularia filamentos*, in which organisms degrade nicotine by demethylation to normnicotine [13]; (2) the pyridine pathway, in which nicotine degradation begins with the hydroxylation of pyridine ring to generate 6-hydroxynicotinic acid, is commonly used by *Arthrobacter* [4], *Nocardoides* [14] and *Rhodococcus* [10] species; (3) pyrrolidine pathway through which nicotine is initially dehydrogenated at the pyrrolidine ring to form N-methylmyosmine, is commonly used by some *Pseudomonas* species [15–18].

In this study, a novel strain, *Pseudomonas geniculata* N1, capable of degrading nicotine was isolated. Along with the identification and characterization of this new nicotine-degrading strain, we also determined the optimal conditions for cell growth and nicotine degradation. Compared with other *Pseudomonas* and *Arthrobacter* species, strain N1 exhibited a distinct color change, during its growth with nicotine as the sole source of carbon and nitrogen. The intermediates of strain N1-mediated nicotine degradation were identified by high-performance liquid chromatography (HPLC), ultraviolet (UV) absorption, gas chromatography mass (GC-MS), and liquid chromatography mass (LC-MS) analysis. The data showed that strain N1 decomposes nicotine via a unique pathway, which is different from those reported by *Pseudomonas* strains. This study suggests that the nicotine-degrading bacterium has future potential application on the treatment of the waste generated during tobacco manufacturing. The findings might help...
Materials and Methods

Chemicals and media

L-(−)-Nicotine (≥99% purity) was purchased from Fluka Chemie GmbH (Buchs, Switzerland). All other chemicals were of analytical grade. The “nic medium” was a minimal medium containing 13.3 g KH₂PO₄·3H₂O, 4 g KH₂PO₄, 0.2 g MgSO₄·7H₂O and 0.5 ml of trace elements solution. L-(−)-Nicotine was added to this minimal medium after filtration sterilization to a final concentration of 0.008 g MnSO₄·7H₂O, and 0.008 g FeCl₂·4H₂O, 0.05 g CaCl₂·2H₂O, 0.05 g CaCl₂·2H₂O, 0.04 g FeCl₃·6H₂O, 0.008 g MnSO₄·H₂O, 0.1 g Na₂MoO₄·2H₂O, 0.05 g Na₂WO₄·2H₂O, and 0.1 g ZnSO₄·7H₂O, followed by 30 cycles of 94°C for 5 min, followed by 30 cycles of 94°C for 30 s, 65°C for 30 s, and 72°C for 3 min. The PCR product was purified for sequence analysis and homology alignment analysis using the BLAST search program (http://www.ncbi.nlm.nih.gov/BLAST.html). A phylogenetic tree was constructed with the neighbor-joining (NJ) method using MEGA 4.1 [19].

A series of experiments were conducted to simultaneously identifying the morphological, physiological and biochemical characteristics of the strain. The morphology was studied using a transmission electron microscope. The physiological and biochemical characteristics such as the utilization of different carbon sources and enzymatic properties were determined by China Center for Type Culture Collection (CCTCC).

Cell growth and nicotine degradation

Culture temperature, pH, nicotine concentration and rotation rates were studied in order to identify the optimal conditions for cell growth and nicotine transformation. To determine the optimal temperature for cell growth, strain N1 was incubated in minimal medium containing 1 g l⁻¹ nicotine at 23°C, 26°C, 30°C, 34°C, and 37°C with the initial pH set at 7.0. The optimal pH was determined by culturing N1 at pH values of 4.5, 5.0, 5.5, 6.0, 6.5, 7.0, and 7.5. The pH was adjusted using 100 mmol phosphoric buffer. Once the optimal temperature and pH were determined, the effect of nicotine concentration (0.5, 1.0, 1.5, and 2.0 g l⁻¹) was investigated under optimal temperature and pH. To evaluate the influence of the rotation rate of the reciprocal shaker on nicotine degradation, strain N1 was cultivated at different shaking rates of 0, 120, 180, and 220 rpm. The optimized conditions were then used for subsequent work.

During the incubation period, aliquots of the culture medium were sampled at the pre-determined intervals and analyzed at 600 nm by using a 2100 spectrophotometer (Unic Company, Shanghai). The samples were also preserved at −20°C for HPLC and UV absorption analyses.

Degradation of nicotine by strain N1

P. geniculata N1 was cultured under optimal conditions in “nic medium”, Luria-Bertani (LB) medium and LB medium with 1 g l⁻¹ nicotine, harvested during the late-exponential phase by centrifugation at 6,000 × g for 8 min at 4°C, and washed twice by sodium phosphate buffer (100 mM, pH 7.0). Then the cells were suspended in deionized water (OD₆₀₀nm ~ 5) for reaction (called resting cells). Resting cells were resuspended in prepared PBS buffer (pH 7.0), and adjusted to OD₆₀₀nm ~ 15, with the addition of 10% glycerol, 1 mM DTT and 2.5 mM PMSE. After sonification in the condition of 3 s on, 5 s off, 90 cycles, cell lysates were centrifuged at 12,000 rpm for 20 min, and the supernatant liquid were used for reaction (called crude cells). The nicotine degradation assay was performed at 30°C on a shaker rotating at 180 rpm.

Identification of metabolites in nicotine degradation

After the “resting cell reaction”, the reaction mixture (1 ml) was evaporated until its dry at 50°C under the reduced pressure, and then dissolved in 200 μl of acetonitrile. The resulting solution was transferred to a vial and dried under nitrogen stream. Samples were analyzed using a GC-MS system (GCD 1800C, Hewlett-Packard) equipped with a flame ionization detector and a 50-m- long, J&W DB-5MS column (Folsom, CA, USA) at 140°C. The injection port and detector were set at 250°C and 280°C, respectively. LC-MS analysis was performed by Agilent 1290 (ultra-performance liquid chromatography, UPLC) coupled with an Agilent 6230 electrospray ionization-time-of-flight-mass spectrometry (ESI-TOF-MS) with methanol-0.1% formic acid mixture.

 Further the research for characterizing the molecular mechanisms underlying nicotine degradation by strain N1.

and H₂O (95.5, v v⁻¹, 0.5 ml min⁻¹). The system was equipped with C18 column (1.8-um thick, 2.1×50 mm; Agilent).

**General analytical techniques**

The nicotine present in the culture medium was quantified by HPLC (Agilent 1200 series) equipped with an Eclipse XDB-C18 column (column size, 250×4.6 mm; particle size, 5 µm; Agilent). A mixture of methanol-1 mmol H₂SO₄ (5:95 v v⁻¹) was used as the mobile phase, at a flow rate of 0.5 ml min⁻¹. Qualitative analysis of nicotine and metabolites was carried out by UV-2500 spectrophotometer (Shimadzu).

**Nucleotide sequence accession number**

The nucleotide sequence reported in the present study has been deposited in the GenBank under the accession number JN607239.

**Results**

**Isolation and identification of strain N1**

The isolated strain N1, which can utilize nicotine as the sole source of carbon and nitrogen, has been deposited at CCTCC under the accession number M2011183. Strain N1 forms small circular, and convex colonies with neat edges on nicotine agar (Figure S1A). Notably, the colonies were yellow, which is rarely observed in case of nicotine-degrading strains. The strain was identified as a non-spore-forming, gram-negative rod (0.5×1.5 µm) with 2 or 3 flagella at one pole. The image of strain N1 is presented in Figure S1B. Strain N1 could utilize a narrow range of carbon sources such as polychrome, and it grew weakly in glucose, amygdalin, arbutin, and saligenin (Table 1). The physiological and biochemical characteristics, performed at CCTCC, are shown in Tables 1 and 2. Strain N1 incubated at 30°C showed the following characteristics: growth at 5% sodium chloride; positive for catalase and oxidase; positive for arginine dihydrogenase and lysine decarboxylase; negative for ornithine decarboxylase; utilization of citric acid or polychrome as the sole source of carbon for growth; positive for lipase (C14); negative for H₂S and indole production; and negative for Voges-Proskauer test (Table 2). The characteristics of strain N1 were strikingly similar to those of previously reported Pseudomonas geniculata strains [20].

The 16S rRNA sequence exhibits 99% identity with Pseudomonas and Stenotrophomonas species. Phylogenetic tree of 16S rRNA from 35 different strains is constructed using the molecular evolutionary genetics analysis tool (MEGA4.1) by neighbor joining [NJ] method and repeated bootstrapping for 1000 times was performed. Strain N1 is closest to the ortholog from Pseudomonas geniculata strain ATCC 19374T (Figure 1). In conclusion, strain N1 was classified as Pseudomonas geniculata based on the above results.

**Cell growth and nicotine degradation**

The effects of temperature on strain N1 is shown in Figure 2A and 2B. Temperature has a dramatic influence on the growth of N1, which showed the maximum rate of growth and nicotine degradation at 30°C. The growth rate was much slower with a gradual drop in temperature. Notably, little-to-no growth was observed at 34°C, which indicates a narrow tolerance range for temperature.

Figure 2C and 2D show the impact of pH on the growth of strain N1. The data show that strain N1 could grow at the pH values ranging from 5.5 to 7.0. Thus, strain N1 prefers weak acidic environment, ranging from pH 6.0 to 6.5. The rate of cell growth dropped remarkably, when pH was <6.0. However, the maximum biomass did not show a major difference. With an increase in the pH value, the cell growth rate dropped slightly in a neutral environment; no growth was detected in an alkaline environment. It should also be noted that the influence of pH on nicotine
degradation was not significant. The degradation rate was rather stable at pH values ranging from 6.0 to 7.5, whereas it was much slower at a pH of 5.5, which was in line with the pattern of cell growth.

Figure 2E and 2F illustrate the nicotine tolerance of strain N1. Strain N1 could grow well when the nicotine concentration was 2 g l$^{-1}$. Moreover, with an increase in the concentration of nicotine in the growth medium, the maximum biomass increased proportionally. However, the growth was much slower when the initial nicotine concentration was 1.5 g l$^{-1}$ rather than 1.0 g l$^{-1}$. The maximum biomass was noted after 4.5 days, when the nicotine concentration was 1.0 g l$^{-1}$, while it took 8 days to reach the stationary phase in the presence of 1.5 g l$^{-1}$ nicotine.

As shown in Figure 2G and 2H, the rotary rate of the shaker can impact cell growth by altering oxygen supply. The growth was extremely slow with low maximum biomass when the growth cultures were kept stationary. This finding confirmed our initial results, which identified strain N1 as an aerobic bacterium. The optimal rotary rate of 120 rpm min$^{-1}$ resulted in the maximum growth rate and maximum biomass production. In conclusion, P. geniculata N1 grows best at 30°C, pH 6.5, and 120 rpm min$^{-1}$ with a maximum nicotine-tolerating capability of 1.5 g l$^{-1}$ (Figure 3).

Nicotine degradation by resting and crude cells

Resting cells harvested from nicotine medium (see materials and methods) were able to degrade 3 g l$^{-1}$ nicotine within 3 h. As shown in Figure 4, the decrease in nicotine concentration and the formation of new peaks in the UV absorption spectrum (Figure 4A) or HPLC spectrum (Figure 4B and Figure S2) suggest the degradation of nicotine and generation of new metabolites. In contrast, the cells cultivated in LB medium did not exhibit the ability to degrade nicotine, illustrating that the enzymes required for nicotine degradation are inducible (Figure S3). The crude cells of strain N1 harvested in nicotine medium were obtained after sonication in phosphate buffer (see materials and methods). However, the cell extracts could not degrade nicotine, and it is similar to the findings with strain Pseudomonas putida S16 [17] (Figure S4).

---

**Figure 1.** Phylogenetic tree of 16S rRNA from 35 different strains. The phylogenetic tree is constructed using the molecular evolutionary genetics analysis tool (MEGA 4.1) by neighbor joining (NJ) method [19]. The repeated bootstrapping for 1,000 times was performed. doi:10.1371/journal.pone.0084399.g001
Nicotine biotransformation and metabolites identification

The culture broth of strain N1 was yellowish green, and blue color did not develop during nicotine biotransformation. This indicated that the nicotine-degradation pathway used differed from that used by *Arthrobacter*, *Nocardioides* and *Rhodococcus* strains. The GC-MS chromatogram is shown in Figure 5. The structures of compound A (nicotine, 12.603 min), B (myosmine, 13.581 min), and E (cotinine, 17.102 min) could be identified by comparing their mass spectra with the standard GC-MS spectral library (Figure 5). Compound C (18.883 min) exhibited the following...
mass spectrum: 178.1 ([M]⁺), 177.1 ([M-H]⁻), 149.1 ([M-C₂H₅]⁻), 135.1 ([M-C₃H₇]⁻), 121.1, 108.1, 84.1 ([M-C₅H₄NO]⁻). The mass spectra were in partial agreement with that of previously reported 6-hydroxy-nicotine [12]. For compound D (15.710 min), its mass spectrum 193.1, 178.1, 166.1, 152.1, 117.1, 103.1, 84.1, 73, and 55.1 was determined, and was found to be identical to those of the trimethylsilyl (TMS) derivative of 6-hydroxy-nicotine. In addition, the molecular ion peaks ([M+H]⁺) of 6-hydroxynicotine (C₁₀H₁₄N₂O), 6-hydroxy-N-methymyosime (C₁₀H₁₂N₂O), 6-hydroxy-pseudooxynicotine (C₁₀H₁₄N₂O₂), and 2,6-dihydroxypseudooxynicotine (C₁₀H₁₄N₂O₃), were shown at m/z 179.1182, 177.1021, 195.1135, and 211.1442 respectively, which were identical to the calculated mass (Figure 6).

**Discussion**

The highly toxic alkaloid nicotine, present in tobacco waste, is removed from the environment via mineralization by bacteria.
Basic insights into the steps and intermediates of nicotine degradation by *Arthrobacter* and *Pseudomonas* species have been proposed and elucidated [4,10,21]. In this study, a novel nicotine-degrading bacterium N1 was isolated from tobacco leaves. The physiological and biochemical data show that the strain N1 belongs to the genus *Pseudomonas*. Most of the morphological and physiological traits of strain N1 were identical to those of *Pseudomonas gniculata* [20]. *P. gniculata* has been poorly reported in previously published literature, and this study is the first report demonstrating the nicotine-degrading ability of *P. gniculata*. In addition, it is interesting that strain N1 could utilize only a narrow range of carbon sources and efficiently degrade nicotine. Strain N1 may have a powerful membrane transport capacity; it has been reported to possess 28 multidrug efflux pump genes [22]. These findings imply a highly efficient nicotine uptake capacity of the strain and an efficient removal of end-products of nicotine catabolism from the cells which may help to explain the nicotine-degrading properties of strain N1.

Current understanding of nicotine degradation in bacteria is based on characterization of 6-hydroxynicotine (pyridine pathway) in *Arthrobacter* species [4] and N-methylpyrrolidine (pyrrolidine pathway) in *Pseudomonas* species [22–25]. Otherwise, *Agrobacterium tumefaciens* strain S33 could firstly transform nicotine to 6-hydroxy-N-methylpyrrolidine using pyridine pathway, and then further degrade 6-hydroxy-N-methylpyrrolidine to 6-hydroxy-3-succinylpyridine and 2,5-dihydroxypyridine using pyrrolidine pathway [12]. In the present study, the formation of blue pigment was not observed during the transformation of nicotine by strain N1. Therefore, it can be proposed that the latter catabolic pathway of nicotine degradation is likely to be different from that of *Arthrobacter*. The intermediates 6-hydroxynicotine, 6-hydroxy-N-methylpyrrolidine, 6-hydroxy-pseudooxynicotine, and 2,6-dihydroxypsuedooxynicotine were identified by GC-MS and LC-MS analyses. The intermediates 6-hydroxy-3-succinylpyridine and 2,5-dihydroxypyridine in *P. putida* S16 were not detected in the “resting cell reactions” of strain N1. It can be concluded that the upper pathway of nicotine degradation in strain N1 was similar to the pyridine pathway, and the further conversion of 2,6-dihydroxypsuedooxynicotine might be different from that observed in *Arthrobacter* and *Pseudomonas*. In addition, the intermediate myosmine and cotinine can be detected by GC-MS. Thus, the direct demethylation to form myosmine and the hydroxylation of nicotine at position 2 of pyrroline ring to form cotinine was proposed, and found to be similar to that of the strain *Pseudomonas* sp. CS3 [26].

In conclusion, it is proposed that the strain *Pseudomonas gniculata* N1 can decompose nicotine via a unique nicotine-degrading pathway.
