Abstract

In this paper, we propose MonoRec, a semi-supervised monocular dense reconstruction architecture that predicts depth maps from a single moving camera in dynamic environments. MonoRec is based on a multi-view stereo setting which encodes the information of multiple consecutive images in a cost volume. To deal with dynamic objects in the scene, we introduce a MaskModule that predicts moving object masks by leveraging the photometric inconsistencies encoded in the cost volumes. Unlike other multi-view stereo methods, MonoRec is able to reconstruct both static and moving objects by leveraging the predicted masks. Furthermore, we present a novel multi-stage training scheme with a semi-supervised loss formulation that does not require LiDAR depth values. We carefully evaluate MonoRec on the KITTI dataset and show that it achieves state-of-the-art performance compared to both multi-view and single-view methods. With the model trained on KITTI, we furthermore demonstrate that MonoRec is able to generalize well to both the Oxford RobotCar dataset and the more challenging TUM-Mono dataset recorded by a handheld camera. Code and related materials are available at https://vision.in.tum.de/research/monorec.

1. Introduction

1.1. Real-world Scene Capture from Video

Obtaining a 3D understanding of the entire static and dynamic environment can be seen as one of the key-challenges in robotics, AR/VR, and autonomous driving. State of today, this is achieved based on the fusion of multiple sensor sources (incl. cameras, LiDARs, RADARs and IMUs). This guarantees dense coverage of the vehicle’s surroundings and accurate ego-motion estimation. However, driven by the high cost as well as the challenge to maintain cross-calibration of such a complex sensor suite, there is an increasing demand of reducing the total number of sensors. Over the past years, researchers have therefore put a lot of effort into solving the problem of perception with only a single monocular camera. Considering recent achievements in monocular visual odometry (VO) [8, 58, 51], with respect to ego-motion estimation, this was certainly successful. Nevertheless, reliable dense 3D mapping of the static environment and moving objects is still an open research topic.

To tackle the problem of dense 3D reconstruction based on a single moving camera, there are basically two paral-
lel lines of research. On one side, there are dense multi-
view stereo (MVS) methods, which evolved over the last
decade [39, 45, 2] and saw a great improvement through the
use of convolutional neural networks (CNNs) [23, 61, 57].
On the other side, there are monocular depth prediction
methods which purely rely on deep learning [7, 16, 58].
Though all these methods show impressive performance,
both types have also their respective shortcomings. For
MVS the overall assumption is a stationary environment to
be reconstructed, so the presence of dynamic objects deteri-
orate their performance. Monocular depth prediction meth-
ods, in contrast, perform very well in reconstructing mov-
ing objects, as predictions are made only based on individ-
ual images. At the same time, due to their use of a single
image only, they strongly rely on the perspective appear-
ance of objects as observed with specific camera intrinsics
and extrinsics and therefore do not generalize well to other
datasets.

1.2. Contribution

To combine the advantage of both deep MVS and
monocular depth prediction, we propose MonoRec, a novel
monocular dense reconstruction architecture that consists of
a MaskModule and a DepthModule. We encode the infor-
mation from multiple consecutive images using cost vol-
umes which are constructed based on structural similarity
index measure (SSIM) [54] instead of sum of absolute dif-
fences (SAD) like prior works. The MaskModule is able
to identify moving pixels and downweights the correspond-
ing voxels in the cost volume. Thereby, in contrast to other
MVS methods, MonoRec does not suffer from artifacts on
moving objects and therefore delivers depth estimations on
both static and dynamic objects.

With the proposed multi-stage training scheme,
MonoRec achieves state-of-the-art performance compared to
other MVS and monocular depth prediction methods on the
KITTI dataset [14]. Furthermore, we validate the generaliza-
tion capabilities of our network on the Oxford
RobotCar dataset [35] and the TUM-Mono dataset [9].
Figure 1 shows a dense point cloud reconstructed by our
method on one of our test sequences of KITTI.

2. Related Work

2.1. Multi-view Stereo

Multi-view stereo (MVS) methods estimate a dense rep-
resentation of the 3D environment based on a set of im-
ages with known poses. Over the past years, several
methods have been developed to solve the MVS problem
[46, 28, 30, 2, 47, 49, 39, 13, 45, 60] based on classical
optimization. Recently, due to the advance of deep neu-
nal networks (DNNs), different learning based approaches
were proposed. This representation can be volumetric
[26, 27, 36] or 3D point cloud based [3, 12]. Most popular
are still depth map representations predicted from a 3D cost
volume [23, 53, 61, 66, 22, 56, 41, 24, 33, 62, 19, 64, 57].
Huang et al. [23] proposed one of the first cost-volume
based approaches. They compute a set of image-pair-wise
plane-sweep volumes with respect to a reference image and
use a CNN to predict one single depth map based on this
set. Zhou et al. [66] also use the photometric cost volumes
as the inputs of the deep neural networks and employ a two
stage approach for dense depth prediction. Yao et al. [61]
instead calculate a single cost volume using deep features
of all input images.

2.2. Dense Depth Estimation in Dynamic Scenes

Reconstructing dynamic scenes is challenging since the
moving objects violate the static-world assumption for clas-
sical multi-view stereo methods. Russell et al. [43] and
Ranftl et al. [40] base on motion segmentation and perform
classical optimization. Li et al. [32] proposed to estimate
dense depth maps from the scenes with moving people. All
these methods need additional inputs, e.g., optical flow, ob-
ject masks, etc., for the inference, while MonoRec requires
only the posed images as the inputs. Another line of re-
search is monocular depth estimation [7, 6, 29, 31, 11, 59,
16, 48, 67, 63, 52, 18, 17, 58]. These methods are not
affected by moving objects, but the depth estimation is not
necessarily accurate, especially in unseen scenarios. Luo
et al. [34] proposed a test-time optimization method which
is not real-time capable. In a concurrent work, Watson et
al. [55] address moving objects with the consistency be-
tween monocular depth estimation and multi-view stereo,
while MonoRec predicts the dynamic masks explicitly by
the proposed MaskModule.

2.3. Dense SLAM

Several of the methods cited above solve both the prob-
lem of dense 3D reconstruction and camera pose estima-
tion [48, 67, 63, 65, 66, 59, 58]. Nevertheless, these meth-
ods either solve both problems independently or only in-
tegrate one into the other (e.g., [66, 58]). Newcombe et
al. [37] instead jointly optimize the 6DoF camera pose and
the dense 3D scene structure. However, due to its volu-
metric map representation it is only applicable to small-
scale scenes. Recently, Bloesch et al. [1] proposed a
learned code representation which can be optimized jointly
with the 6DoF camera poses. This idea is pursued by
Czarnowski et al. [3] and integrated into a full SLAM sys-
tem. All the above-mentioned methods, however, do not
address the issue of moving objects. Instead, the proposed
MonoRec network explicitly deals with moving objects and
achieves superior accuracy both on moving and on static
structures. Furthermore, prior works show that the accuracy
of camera tracking does not necessarily improve with more
points [8, 10]. MonoRec therefore focuses solely on delivering dense reconstruction using poses from a sparse VO system and shows state-of-the-art results on public benchmarks. Note that, this way, MonoRec can be easily combined with any VO systems with arbitrary sensor setups.

3. The MonoRec Network

MonoRec uses a set of consecutive frames and the corresponding camera poses to predict a dense depth map for the given keyframe. The MonoRec architecture combines a MaskModule and a DepthModule. MaskModule predicts moving object masks that improve depth accuracy and allows us to eliminate noise in 3D reconstructions. DepthModule predicts a depth map from the masked cost volume. In this section, we first describe the different modules of our architecture, and then discuss the specialized multi-stage semi-supervised training scheme.

3.1. Preliminaries

Our method aims to predict a dense inverse depth map $D_t$ of the selected keyframe from a set of consecutive frames $\{I_1, \ldots, I_N\}$. We denote the selected keyframe as $I_t$ and others as $I_t^t$ ($t' \in \{1, \ldots, N\} \setminus t$). Given the camera intrinsics, the inverse depth map $D_t$, and the relative camera pose $T_{t'} \in SE(3)$ between $I_t$ and $I_t$, we can perform the reprojection from $I_t^t$ to $I_t$ as

$$I_t^t = I_t \langle proj (D_t, T_{t'}) \rangle,$$  \hspace{1cm} (1)

where $proj()$ is the projection function and $\langle \rangle$ is the differentiable sampler [25]. This reprojection formulation is important for both the cost volume formation (Sec. 3.2) and the self-supervised loss term (Sec. 3.4).

In the following, we refer to the consecutive frames as temporal stereo (T) frames. During training, we use an additional static stereo (S) frame $I_t^s$ for each sample, which was captured by a synchronized stereo camera at the same time as the respective keyframe.

3.2. Cost Volume

A cost volume encodes geometric information from the different frames in a tensor that is suited as input for neural networks. For a number of discrete depth steps, the temporal stereo frames are reprojected to the keyframe and a pixel-wise photometric error is computed. Ideally, the lower the photometric error, the better the depth step approximates the real depth at a given pixel. Our cost volume follows the general formulation of the prior works [37, 66]. Nevertheless, unlike the previous works that define the photometric error $pe()$ as a patch-wise SAD, we propose to use the SSIM as follows:

$$pe(x, d) = \frac{1 - \text{SSIM}(I_t^t(x, d), I_t(x))}{2}$$ \hspace{1cm} (2)

with $3 \times 3$ patch size. Here $I_t^t(x, d)$ defines the intensity at pixel $x$ of the image $I_t^t$ warped with constant depth $d$. In practice, we clamp the error to $[0, 1]$. The cost volume $C$ stores at $C(x, d)$ the aggregated photometric consistency for pixel $x$ and depth $d$

$$C(x, d) = 1 - \frac{1}{\sum_{t'} \omega_{t'}} \cdot \sum_{t'} pe_{t'}(x, d) \cdot \omega_{t'}(x)$$ \hspace{1cm} (3)

where $d \in \{d|d_{min} + \frac{i}{M} \cdot (d_{min} - d_{max})\}$. The weighting term $\omega_{t'}(x)$ weights the optimal depth step height based on the photometric error while others are weighted lower:

$$\omega_{t'}(x) = 1 - \frac{1}{M - 1} \cdot \sum_{\tilde{d} \neq d^*} \exp \left( -\alpha \left( pe_{t'}(x, d) - pe_{t'}(x, \tilde{d}) \right)^2 \right)$$ \hspace{1cm} (4)

with $d^* = \arg \min_d pe_{t'}(x, d)$. Note that $C(x, d)$ has the range $[-1, 1]$ where $-1/1$ indicates the lowest/highest photometric consistency.

In the following section, we denote cost volumes calculated based on the keyframe $I_t$ and only one non-keyframe $I_t^t$ by $C_{t'}(x, d)$ where applicable.
3.3. Network Architecture

As shown in Figure 2, the proposed network architecture contains two sub-modules, namely, MaskModule and DepthModule.

MaskModule MaskModule aims to predict a mask $M_t$ where $M_t(x) \in [0, 1]$ indicates the probability of a pixel $x$ in $I_t$ belonging to a moving object. Determining moving objects from $I_t$ alone is an ambiguous task and hard to be generalizable. Therefore, we propose to use the set of cost volumes $\{C_t'[t'] \in \{1, \ldots, N\} \setminus t\}$ which encode the geometric priors between $I_t$ and $\{I_t'[t'] \in \{1, \ldots, N\} \setminus t\}$ respectively. We use $C_t'$ instead of $C$ since the inconsistent geometric information from different $C_t'$ is a strong prior for moving object prediction – dynamic pixels yield inconsistent optimal depth steps in different $C_t'$. However, geometric priors alone are not enough to predict moving objects, since poorly-textured or non-Lambertian surfaces can lead to inconsistencies as well. Furthermore, the cost volumes tend to reach a consensus on wrong depths that semantically don’t fit into the context of the scene for objects that move at constant speed. Therefore, we further leverage pre-trained ResNet-18 $I_t$ with skip connections. All cost volumes are passed through the encoders with shared weights. The features from different cost volumes are aggregated using max-pooling and then passed through the decoder. In this way, MaskModule can be applied to different numbers of frames without retraining.

DepthModule DepthModule predicts a dense pixel-wise inverse depth map $D_t$ of $I_t$. To this end, the module receives the complete cost volume $C$ concatenated with the keyframe $I_t$. Unlike MaskModule, here we use $C$ instead of $C_t'$ since multi-frame cost volumes in general lead to higher depth accuracy and robustness against photometric noise [37]. To eliminate wrong depth predictions for moving objects, we perform pixel-wise multiplication between $M_t$ and the cost volume $C$ for every depth step $d$. This way, there won’t be any maxima (i.e. strong priors) in regions of moving objects left, such that DepthModule has to rely on information from the image features and the surroundings to infer the depth of moving objects. We employ a U-Net architecture with multi-scale depth outputs from the decoder [17]. Finally, DepthModule outputs an interpolation factor between $d_{\text{min}}$ and $d_{\text{max}}$. In practice, we use $s = 4$ scales of depth prediction.

3.4. Multi-stage Training

In this section, we propose a multi-stage training scheme for the networks. Specifically, the bootstrapping stage, the

Figure 3: Auxiliary Training Masks: Examples of auxiliary training masks from the training set that are used as reference.

Bootstrapping In the bootstrapping stage, MaskModule and DepthModule are trained separately. DepthModule takes the non-masked $C$ as the input and predicts $D_t$. The training objective of DepthModule is defined as a multi-scale ($s \in [0,3]$) semi-supervised loss. It combines a self-supervised photometric loss and an edge-aware smoothness term, as proposed in [17], with a supervised sparse depth loss.

$$L_{\text{depth}} = \sum_{s=0}^{3} L_{\text{self},s} + \alpha L_{\text{sparse},s} + \beta L_{\text{smooth},s}.$$ \hspace{1cm} (5)

The self-supervised loss is computed from the photometric errors between the keyframe and the reprojected temporal stereo and static stereo frames:

$$L_{\text{self},s} = \min_{t' \in \{t\cup\{t^s\}} \left( \frac{1 - \text{SSIM}(I_t^s, I_t)}{2} \right) + (1 - \lambda) ||I_t^s - I_t||_1 \right),$$ \hspace{1cm} (6)

where $\lambda = 0.85$. Note that $L_{\text{self},s}$ takes the per-pixel minimum which has been shown to be superior compared to the per-pixel average [17]. The sparse supervised depth loss is defined as

$$L_{\text{sparse},s} = ||D_t - D_{\text{VO}}||_1,$$ \hspace{1cm} (7)

where the ground-truth sparse depth maps ($D_{\text{VO}}$) are obtained by a visual odometry system [59]. Note that all the supervision signals of DepthModule are generated from either images themselves or the visual odometry system without any manual labeling or LiDAR depth.

MaskModule is trained with the mask loss $L_{\text{mask}}$ which is the weighted binary cross entropy between the predicted mask $M_t$ and the auxiliary ground-truth moving object mask $M_{\text{aux}}$. We generate $M_{\text{aux}}$ by leveraging a pre-trained Mask-RCNN and the trained DepthModule as explained above. We firstly define the movable object classes, e.g., cars, cyclists, etc, and then obtain the instance segmentations of these object classes for the training images. A movable instance is classified as a moving instance if it
has a high ratio of photometrically inconsistent pixels between temporal stereo and static stereo. Specifically, for each image, we predict its depth maps $D_t$ and $D_t^S_i$ using the cost volumes formed by temporal stereo images $C$ and static stereo images $C^S$, respectively. Then a pixel $x$ is regarded as a moving pixel if two of the following three metrics are above predefined thresholds: (1) The static stereo photometric error using $D_t$, i.e., \( pe_b^S(x, D_t(x)) \). (2) The average temporal stereo photometric error using $D_t^S$, i.e., \( \bar{pe}_b^S(x, D_t^S(x)) \). (3) The difference between $D_t(x)$ and $D_t^S(x)$. Please refer to our supplementary materials for more details. Figure 3 shows some examples of the generated auxiliary ground-truth moving object masks.

### MaskModule Refinement

The bootstrapping stage for MaskModule is limited in two ways: (1) Heavy augmentation is needed since mostly only a very small percentage of pixels on the image belongs to moving objects. (2) The auxiliary masks are not necessarily related to the geometric prior in the cost volume, which slows down the convergence. Therefore, to improve the mask prediction, we utilize the trained DepthModule from the bootstrapping stage. We leverage the fact that the depth prediction for age of pixels on the image belongs to moving objects. (2) MaskModule is limited in two ways: (1) Heavy augmentation. Figure 4(a) shows the diagram illustrating different loss terms. Note that we still add the supervised mask loss $\mathcal{L}_{mask}$ as a regularizer to stabilize the training. This way, the new gradients are directly related to the geometric structure in the cost volume and help to improve the mask prediction accuracy and alleviate the danger of overfitting.

### DepthModule Refinement

The bootstrapping stage does not distinguish between the moving pixels and static pixels when training DepthModule. Therefore, we aim to refine DepthModule such that it is able to predict proper depths also for moving objects. The key idea is that, by utilizing $M_t$, only the static stereo loss is backpropagated for moving pixels, while for static pixels the temporal stereo, static and sparse depth losses are backpropagated. Because moving objects make up only a small percentage of all pixels in a keyframe, the gradients from the photometric error are rather weak. To solve this, we perform a further static stereo forward pass and use the resulting depth map $D_t^S$ as prior for moving objects. Therefore, as shown in Figure 4(b), the loss for refining DepthModule is defined as

\[
\mathcal{L}_{d,ref,s} = (1 - M_t) (\mathcal{L}_{self,s} + \alpha \mathcal{L}_{sparse,s}) + \beta \mathcal{L}_{smooth,s},
\]

where $\mathcal{L}_{self,s}$, $\mathcal{L}_{sparse,s}$, and $\mathcal{L}_{smooth,s}$ are the losses for self, sparse, and smoothness, respectively.

3.4.1 Implementation Details

The networks are implemented in PyTorch [38] with image size $512 \times 256$. For the bootstrapping stage, we train DepthModule for 70 epochs with learning rate $lr = 1e^{-4}$ for the first 65 epochs and $lr = 1e^{-5}$ for the remaining ones. MaskModule is trained for 60 epochs with $lr = 1e^{-4}$. During MaskModule refinement, we train for 32 epochs with $lr = 1e^{-4}$, and during DepthModule refinement we train for 15 epochs with $lr = 1e^{-4}$ and another 4 epochs at $lr = 1e^{-5}$. The hyperparameters $\alpha$, $\beta$, and $\gamma$ are set to 4, $10^{-3} \times 2^{-s}$, and 4, respectively. For inference, MonoRec can achieve 10 fps with batch size 1 using 2GB memory.

4. Experiments

To evaluate the proposed method, we first compare against state-of-the-art monocular depth prediction and MVS methods with our train/test split of the KITTI dataset [15]. Then, we perform extensive ablation studies to show the efficacy of our design choices. In the end, we demonstrate the generalization capabilities of different methods on Oxford RobotCar [35] and TUM-Mono [9] using the model trained on KITTI.
Figure 5: **Qualitative Results on KITTI**: The upper part of the figure shows the results for a selected number of frames from the KITTI test set. The compared PackNet model was trained in a semi-supervised fashion using LiDAR as the ground truth. Besides the depth maps, we also show the 3D point clouds by reprojecting the depth and viewing from two different perspectives. For comparison we show the LiDAR ground truth from the corresponding perspectives. Our method clearly shows the best prediction quality. The lower part of the figure shows large scale reconstructions as point clouds accumulated from multiple frames. The red insets depict the reconstructed artifacts from moving objects. With the proposed MaskModule, we can effectively filter out the moving objects to avoid those artifacts in the final reconstruction.
Table 1: Quantitative Results on KITTI: Comparison between MonoRec and other methods on our KITTI test set. The Dataset column shows the training dataset used by the corresponding method and please note that Eigen split is a superset of our odometry split. Best / Second best results are marked bold / underlined. The evaluation result shows that our method achieves overall the best performance. Figure 6: Qualitative Improvement: Effects of cost volume masking and depth refinement.

4.1. The KITTI Dataset

The Eigen split [6] is the most popular training/test split for evaluating depth estimation on KITTI. We cannot make use of it directly since MonoRec requires temporally continuous images with estimated poses. Hence, we select our training/testing splits as the intersection between the KITTI Odometry benchmark and the Eigen split, which results in 13714/8634 samples for training/testing. We obtain the relative poses between the images from the monocular VO system DVSO [59]. During training, we also leverage the point clouds generated by DVSO as the sparse depth supervision signals. For training MaskModule we only use images that contain moving objects in the generated auxiliary masks, 2412 in total. For all the following evaluation results we use the improved ground truth [50] and cap depths at 80 m.

We first compare our method against the recent state of the art including an optimization based method (Colmap), self-supervised monocular methods (MonoDepth2 and PackNet), a semi-supervised monocular method using sparse LiDAR data (PackNet), a supervised monocular method (DORN) and MVS methods (DeepMVS and DeepTAM), shown in Table 1. Note that the training code of DeepTAM was not published, we therefore implemented it ourselves for training and testing using our split to deliver a fair comparison. Our method outperforms all the other methods with a notable margin despite relying on images only without using LiDAR ground truth for training.

This is also clearly reflected in the qualitative results shown in Figure 5. Compared with monocular depth estimation methods, our method delivers very sharp edges in the depth maps and can recover finer details. In comparison to the other MVS methods, it can better deal with moving objects, which is further illustrated in Figure 7.

A single depth map usually cannot really reflect the quality for large scale reconstruction. We therefore also visualize the accumulated points using the depth maps from multiple frames in lower part of Figure 5. We can see that our method can deliver very high quality reconstruction and, due to our MaskModule, is able to remove artifacts caused by moving objects. We urge readers to watch the supplementary video for more convincing comparisons.

### Ablation Studies

We also investigated the contribution of the different components towards the method’s performance. Table 2 shows quantitative results of our ablation studies, which confirm that all our proposed contributions improve the depth prediction over the baseline method. Furthermore, Figure 6 demonstrates the qualitative improvement achieved by MaskModule and refinement training.

4.2. Oxford RobotCar and TUM-Mono

To demonstrate the generalization capabilities of MonoRec, we test our KITTI model on the Oxford RobotCar dataset and the TUM-Mono dataset. Oxford RobotCar is a street view dataset and shows a similar motion pattern and view perspective to KITTI. TUM-Mono, however, is recorded by a handheld monochrome camera, so it demon-
| Model     | SSIM | MaskModule | D. Ref. | M. Ref. | Abs Rel | Sq Rel | RMSE  | RMSE_{1.25} | δ < 1.25 | δ < 1.25^2 | δ < 1.25^3 |

Table 2: Ablation Study: Baseline consists of only DepthModule using the unmasked cost volume (CV). Baseline without SSIM uses a 5x5 patch that has same receptive field as SSIM. Using SSIM to form CV gives a significant improvement. For MonoRec, only the addition of MaskModule without refinement does not yield significant improvements. The DepthModule refinement gives a major improvement. The best performance is achieved by combining all the proposed components.

![Figure 7](image1.png)

Figure 7: Comparison on Moving Objects Depth Estimation: In comparison to other MVS methods, MonoRec is able to predict plausible depths. Furthermore, the depth prediction has less noise and artifacts in static regions of the scene.

![Figure 8](image2.png)

Figure 8: Oxford RobotCar and TUM-Mono: All results are obtained by the respective best-performing variant in Table 1. MonoRec shows stronger generalization capability than the monocular methods. Compared to DeepMVS and DeepTAM, MonoRec delivers depth maps with less artifacts and predicts the moving object masks in addition.

5. Conclusion

We have presented MonoRec, a deep architecture that estimates accurate dense 3D reconstructions from only a single moving camera. We first propose to use SSIM as the photometric measurement to construct the cost volumes. To deal with dynamic objects, we propose a novel MaskModule which predicts moving object masks from the input cost volumes. With the predicted masks, the proposed DepthModule is able to estimate accurate depths for both static and dynamic objects. Additionally, we propose a novel multi-stage training scheme together with a semi-supervised loss formulation for training the depth prediction. All combined, MonoRec is able to outperform the state-of-the-art MVS and monocular depth prediction methods both qualitatively and quantitatively on KITTI and also shows strong generalization capability on Oxford RobotCar and TUM-Mono. We believe that this capacity to recover accurate dense 3D reconstructions from a single moving camera will help to establish the camera as the lead sensor for autonomous systems.
