Abstract

The deployment of DeepCore array significantly lowers IceCube's energy threshold to about 10 GeV and enhances the sensitivity of detecting neutrinos from annihilations and decays of light dark matter. To match this experimental development, we calculate the track event rate in DeepCore array due to neutrino flux produced by annihilations and decays of galactic dark matter. We also calculate the background event rate due to atmospheric neutrino flux for evaluating the sensitivity of DeepCore array to galactic dark matter signatures. Unlike previous approaches, which set the energy threshold for track events at around 50 GeV (this choice avoids the necessity of including oscillation effect in the estimation of atmospheric background event rate), we have set the energy threshold at 10 GeV to take the full advantage of DeepCore array. We compare our calculated sensitivity with those obtained by setting the threshold energy at 50 GeV. We conclude that our proposed threshold energy significantly improves the sensitivity of DeepCore array to the dark matter signature for $m_\chi < 100$ GeV in the annihilation scenario and $m_\chi < 300$ GeV in the decay scenario.

I. INTRODUCTION

Many astrophysical observations have confirmed the existence of dark matter (DM), which contributes to roughly 23% of the energy density of the Universe. Among many proposed DM candidates, weakly interacting massive particles (WIMPs) \cite{1,2} are popular proposals since they are theoretically well motivated and also capable of producing the correct relic density. WIMPs could annihilate or decay into particles such as electrons, positrons, protons, antiprotons, photons, and neutrinos. It is possible to establish the WIMP signature through detecting these particles \cite{3–15}.

Research activities on WIMPs have been boosted recently in efforts of explaining the observed anomalous positron excess in the data of PAMELA \cite{8} and positron plus electron excess in the data of FERMI \cite{12}. To account for spectral shapes observed by these experiments, WIMPs must annihilate or decay mostly into leptons in order to avoid the overproduction of antiprotons. This could indicate that DM particles are leptophilic in their annihilations or decays \cite{16,17}. It has been pointed out that the observation of neutrinos can give stringent constraints on the above scenario. Measurements of upward going muons by Super-Kamiokande observatory place a limit on the galactic muon neutrino flux, which in turn rules out the possibility of WIMP annihilations to $\tau^+\tau^-$ as a source of $e^\pm$ anomalies \cite{18–20}. Furthermore, one expects that the possibilities of WIMP annihilations into $\mu^\pm$, and WIMP decays into $\mu^\pm$ and $\tau^\pm$ will all be stringently constrained \cite{21–23} (see also discussions in Ref. \cite{24}) by the data from IceCube detector augmented with DeepCore array.

The DeepCore array \cite{25,26} is located in the deep center region of IceCube detector. This array consists of 6 densely instrumented strings plus 7 nearest standard IceCube strings. The installation of DeepCore array significantly improves the rejection of downward going atmospheric muons in IceCube and lowers the threshold energy for detecting muon track or cascade events to about 5 GeV. As summarized in Ref. \cite{26}, the low detection threshold of DeepCore array is achieved by three improvements over the IceCube detector. First, the photo-sensors in DeepCore are more densely instrumented than those of IceCube, as just mentioned. Second, the ice surrounding the DeepCore array is on average twice as clear as the average ice above 2000 m \cite{27}. Such a property is useful for reconstructing lower-energy neutrino events. Finally the DeepCore array uses new type of phototube which has a higher quantum efficiency.
It is clear that DeepCore array improves the sensitivity as well as enlarges the energy window for observing neutrinos from DM annihilations or decays in the galactic halo. Previous analyses on the detection of these neutrinos in DeepCore [23, 28] have set the threshold energy at $(40-50)$ GeV for both track and cascade events. For neutrino events with energies higher than 50 GeV, the estimation of atmospheric background event rate is straightforward since oscillation effects can be neglected. However, to take the full advantage of DeepCore array, it is desirable to estimate the track and shower event rates due to atmospheric neutrinos in the energy range $10 \, \text{GeV} \leq E_\nu \leq 50 \, \text{GeV}$. In this energy range, the oscillations of atmospheric neutrinos cannot be neglected. In this article, we take into account this oscillation effect and calculate the track event rate with a threshold energy $E^{\text{th}}_\mu = 10 \, \text{GeV}$ due to atmospheric muon neutrinos from all zenith angles. Given such a background event rate, we then evaluate the sensitivities of DeepCore array to the neutrino flux arising from DM annihilations and decays in the galactic halo. In the subsequent paper, we shall analyze the corresponding sensitivities associated with cascade events.

This paper will focus on neutrino signature induced by low-mass DM. Hence our interested DM mass range is far below TeV level implied by PAMELA and FERMI data. Therefore we shall consider neutrino flux induced by DM annihilations/decays into both leptons and hadrons. Specifically, we consider the channels $\chi\chi \rightarrow b\bar{b}, \tau^+\tau^-$, and $\mu^+\mu^-$ for annihilations and the channels $\chi \rightarrow b\bar{b}, \tau^+\tau^-$ and $\mu^+\mu^-$ for decays. Since we are only interested in low-mass dark matter, we have neglected neutrino fluxes generated through DM annihilations or decays into $t\bar{t}, W^+W^-$ and $ZZ$ final states. We also neglect neutrino fluxes arising from light meson decays, as the annihilation cross section for $\chi\chi \rightarrow q\bar{q}$ is likely to be suppressed by $m_q^2 [2]$. We shall compare the constraints on DM annihilation cross section and DM decay time for different values of threshold energy $E^{\text{th}}_\mu$. For such a comparison, we employ the modes $\chi\chi \rightarrow \mu^+\mu^-$ and $\chi \rightarrow \mu^+\mu^-$ for illustrations.

This paper is organized as follows. In Sec. II, we outline the calculation of muon neutrino flux from WIMP annihilations and decays in the galactic halo. In Sec. III, we calculate the atmospheric muon neutrino flux from all zenith angles with $E_\nu \geq 10 \, \text{GeV}$. The oscillations between $\nu_\mu$ and $\nu_\tau$ are taken into account. In Sec. IV, we evaluate the sensitivity of DeepCore array to neutrino flux arising from WIMP annihilations or decays in the galactic halo. We compare our results with those obtained by setting $E^{\text{th}}_\mu = 50 \, \text{GeV}$. We summarize in Sec. V.
II. NEUTRINO FLUX FROM ANNIHILATIONS AND DECAYS OF DARK MATTER IN THE GALACTIC HALO

The differential neutrino flux from the galactic dark matter halo for neutrino flavor $i$ can be written as

$$\frac{d\Phi_{\nu_i}}{dE_{\nu_i}} = \frac{\Delta\Omega}{4\pi} \frac{\langle \sigma v \rangle}{2m_{\chi}^2} \left( \sum_F B_F \frac{dN_{\nu_i}^F}{dE} \right) R_{\odot}\rho_{\odot}^2 \times J_2(\Delta\Omega)$$

(1)

for the case of annihilating DM, and

$$\frac{d\Phi_{\nu_i}}{dE_{\nu_i}} = \frac{\Delta\Omega}{4\pi} \frac{1}{m_{\chi}\tau_{\chi}} \left( \sum_F B_F \frac{dN_{\nu_i}^F}{dE} \right) R_{\odot}\rho_{\odot} \times J_1(\Delta\Omega)$$

(2)

for the case of decaying DM, where $R_{\odot} = 8.5$ kpc is the distance from the galactic center (GC) to the solar system, $\rho_{\odot} = 0.3$ GeV/cm$^3$ is the DM density in the solar neighborhood, $m_{\chi}$ is the DM mass, $\tau_{\chi}$ is the DM decay time and $dN_{\nu_i}^F/dE$ is the neutrino spectrum per annihilation or decay for a given annihilation or decay channel $F$ with a corresponding branching fraction $B_F$. The neutrino spectra $dN_{\nu_i}^F/dE$ for different channels are summarized in Ref [28, 29]. The quantity $\langle \sigma v \rangle$ is the thermally averaged annihilation cross section, which can be written as

$$\langle \sigma v \rangle = B \langle \sigma v \rangle_0,$$

(3)

with a boost factor $B$ [30, 31]. We set $\langle \sigma v \rangle_0 = 3 \times 10^{-26}$ cm$^3$s$^{-1}$, which is the typical annihilation cross section for the present dark matter abundance under the standard thermal relic scenario [1]. We treat the boost factor $B$ as a phenomenological parameter. The dimensionless quantity $J_n(\Delta\Omega)$ is the DM distribution integrated over the line-of-sight (l.o.s) and averaged over a solid angle $\Delta\Omega = 2\pi(1 - \cos\psi_{\text{max}})$, i.e.,

$$J_n(\Delta\Omega) = \frac{1}{\Delta\Omega} \int_{\Delta\Omega} d\Omega \int_{\text{l.o.s}} \frac{dl}{R_{\odot}} \left( \frac{\rho(l, \psi)}{\rho_{\odot}} \right)^n,$$

(4)

where $\rho$ is the DM density at a specific location described by the coordinate $(l, \psi)$ with $l$ the distance from the Earth to DM and $\psi$ the direction of DM viewed from the Earth with $\psi = 0$ corresponding to the direction of GC. The distance $r \equiv \sqrt{R_{\odot}^2 + l^2 - 2R_{\odot}l\cos\psi}$ is the distance from GC to DM. The upper limit of the integration, $l_{\text{max}} \equiv R_{\odot}\cos\psi + \sqrt{R_{\odot}^2 - R_{\odot}^2\sin^2\psi}$,
depends on $R_s$, the adopted size of the galactic halo. In this analysis, we take $R_s = 20$ kpc and use the Navarro-Frenk-White (NFW) DM density profile [32]

$$\rho(r) = \rho_s \left( \frac{R_s}{r} \right)^{2} \left( \frac{R_s}{R_s + r} \right)^{2},$$

(5)

with $\rho_s = 0.26$ GeVcm$^{-3}$ such that $\rho_\odot = 0.3$ GeVcm$^{-3}$.

Neutrinos are significantly mixed through oscillations when they travel a vast distance across the galaxy. We determine neutrino flavor oscillation probabilities in the tribimaximal limit [33] of neutrino mixing angles, i.e., $\sin^2 \theta_{23} = 1/2$, $\sin^2 \theta_{12} = 1/3$ and $\sin^2 \theta_{13} = 0$. The neutrino fluxes on Earth are related to those at the source through [34–36]

$$\Phi_{\nu_e} = \frac{5}{9} \Phi^0_{\nu_e} + \frac{2}{9} \Phi^0_{\nu_\mu} + \frac{2}{9} \Phi^0_{\nu_\tau},$$

(6)

and

$$\Phi_{\nu_\mu} = \Phi_{\nu_\tau} = \frac{2}{9} \Phi^0_{\nu_e} + \frac{7}{18} \Phi^0_{\nu_\mu} + \frac{7}{18} \Phi^0_{\nu_\tau},$$

(7)

where $\Phi^0_{\nu_i}$ is the neutrino flux of flavor $i$ at the astrophysical source. It is understood that the recent T2K [37] and Double Chooz [38] experiments have indicated a non-zero value for $\theta_{13}$. Taking the T2K best-fit value $\sin^2 2\theta_{13} = 0.11$ at the CP phase $\delta = 0$ for the normal mass hierarchy, we have

$$\Phi_{\nu_e} = 0.53 \Phi^0_{\nu_e} + 0.26 \Phi^0_{\nu_\mu} + 0.21 \Phi^0_{\nu_\tau},$$

$$\Phi_{\nu_\mu} = 0.26 \Phi^0_{\nu_e} + 0.37 \Phi^0_{\nu_\mu} + 0.37 \Phi^0_{\nu_\tau},$$

$$\Phi_{\nu_\tau} = 0.21 \Phi^0_{\nu_e} + 0.37 \Phi^0_{\nu_\mu} + 0.42 \Phi^0_{\nu_\tau}.$$  

(8)

To proceed our discussions, let us first take the neutrinos at the source to be those generated by $B$ meson decays following the $\chi \chi \to b \bar{b}$ annihilation. In this special case, $\Phi^0_{\nu_e} = \Phi^0_{\nu_\mu} = \Phi^0_{\nu_\tau}$ at the source, and consequently the relation $\Phi_{\nu_e} = \Phi_{\nu_\mu} = \Phi_{\nu_\tau}$ always holds due to the probability conservation, irrespective of the form of oscillation probability matrix. Let us now consider neutrinos produced at the source by muon decays following the $\chi \chi \to \mu^+ \mu^-$ annihilation. In this case, one has $\Phi^0_{\nu_e} = \Phi^0_{\nu_\mu}$ and $\Phi^0_{\nu_\tau} = 0$. Taking $\Phi^0_{\nu_e} = \Phi^0_{\nu_\mu} \equiv \Phi^0$, one obtains $\Phi_{\nu_e} = 0.78 \Phi^0$ and $\Phi_{\nu_\mu} = \Phi_{\nu_\tau} = 0.61 \Phi^0$ for tribimaximal values of neutrino mixing parameters. On the other hand, with the T2K best-fit $\theta_{13}$ value, one arrives at $\Phi_{\nu_e} = 0.79 \Phi^0$, $\Phi_{\nu_\mu} = 0.63 \Phi^0$ and $\Phi_{\nu_\tau} = 0.58 \Phi^0$ for the normal mass hierarchy. Clearly $\Phi_{\nu_e}$
is almost unaffected while $\Phi_{\nu_\mu}/\Phi_{\nu_\tau} - 1 = 9\%$. For the inverted mass hierarchy, one obtains the same $\nu_e$ flux while $\Phi_{\nu_\mu}/\Phi_{\nu_\tau} - 1 = 12\%$. Hence T2K result implies an $O(10\%)$ difference between the arrival $\nu_\mu$ and $\nu_\tau$ fluxes for neutrinos produced by $\chi \chi \rightarrow \mu^+ \mu^-$ annihilations.

III. ATMOSPHERIC NEUTRINO FLUXES

Knowing atmospheric neutrino background is important for evaluating the sensitivity of DeepCore array to neutrino flux from DM annihilations or decays. We begin by computing the flux of intrinsic atmospheric muon neutrinos arising from pion and kaon decays, following the approaches in Refs. [39, 40]. The $\nu_\mu$ flux arising from $\pi$ decays can be written as

$$
\frac{d^2 N_{\nu_\mu}(E, \xi, X)}{dEdX} = \int_E^\infty dE_N \int_{E_N}^{E} dE_\pi \frac{\Theta(E_\pi - \frac{E}{1 - \gamma_\pi})}{d_\pi E_\pi (1 - \gamma_\pi)} \times \int_0^X \frac{dX'}{\lambda_N} P_\pi(E_\pi, X, X') \frac{1}{E_\pi} F_{N\pi}(E_\pi, E_N) \times \exp \left( -\frac{X'}{\Lambda_N} \right) \phi_N(E_N),
$$

(9)

where $E$ is the neutrino energy, $X$ is the slant depth in units of g/cm$^2$, $\xi$ is the zenith angle in the direction of incident cosmic-ray nucleons, $r_\pi = m_\mu^2/m_{\pi}^2$, $d_\pi$ is the pion decay length in units of g/cm$^2$, $\lambda_N$ is the nucleon interaction length and $\Lambda_N$ is the corresponding nucleon attenuation length. The function $P_\pi(E_\pi, X, X')$ is the probability that a charged pion produced at the slant depth $X'$ survives to the depth $X (> X')$, which is given by [43]

$$
P_\pi(E_\pi, X, X') = \exp \left( -\frac{X - X'}{\Lambda_\pi} \right) \cdot \exp \left( -\frac{m_\pi c}{E_\pi \tau_\pi} \int_{X'}^{X} dT \rho(T) \right),
$$

(10)

where $\Lambda_\pi = 160$ g/cm$^2$ is the pion attenuation length, $\tau_\pi$ is the pion lifetime at its rest frame, while $\rho(T)$ is the atmosphere mass density at the slant depth $T$. Finally, $F_{N\pi}(E_\pi, E_N)$ is the normalized inclusive cross section for $N + \text{air} \rightarrow \pi^± + Y$, which is given by [39]

$$
F_{N\pi}(E_\pi, E_N) \equiv \frac{E_\pi}{\sigma_N} \frac{d\sigma(E_\pi, E_N)}{dE_\pi} = c_+(1 - x)^{p_+} + c_- (1 - x)^{p_-},
$$

(11)

with $x = E_\pi/E_N$, $c_+ = 0.92$, $c_- = 0.81$, $p_+ = 4.1$, and $p_- = 4.8$.

The primary cosmic-ray spectrum $\phi_N(E_N)$ in Eq. (9) includes contributions from cosmic ray protons and those from heavier nuclei. We have $\phi_N(E_N) = \sum_A A \phi_A(E_N)$ with $A$ the atomic number of each nucleus. The spectrum of each cosmic-ray component is parametrized by [41, 42]

$$
\phi_A(E_N) = K \times (E_N + b \exp[-c \sqrt{E_N}])^{-\alpha},
$$

(12)
TABLE I: Parameters for all five components in the fit of Eq. (12).

| parameter/component | $\alpha$ | $K$  | $b$  | $c$  |
|----------------------|----------|------|------|------|
| Hydrogen (A=1) ($\leq 10^2$GeV) | 2.74 | 14900 | 2.15 | 0.21 |
| Hydrogen (A=1) ($> 10^2$GeV) | 2.71 | 14900 | 2.15 | 0.21 |
| He (A=4) | 2.64 | 600 | 1.25 | 0.14 |
| CNO (A=14) | 2.60 | 33.2 | 0.97 | 0.01 |
| Mg-Si (A=25) | 2.79 | 34.2 | 2.14 | 0.01 |
| Iron (A=56) | 2.68 | 4.45 | 3.07 | 0.41 |

in units of $m^{-2}s^{-1}sr^{-1}GeV^{-1}$. The fitting parameters $\alpha, K, b, c$ depend on the type of nucleus. They are tabulated in Table I [42]. The kaon contribution to the atmospheric $\nu_\mu$ flux has the same form as Eq. (9) with an inclusion of the branching ratio $B(K \to \mu\nu) = 0.635$ and appropriate replacements in kinematic factors and the normalized inclusive cross section. In particular, $F_{NK}(E_K, E_N)$ can be parametrized as Eq. (11) with $c_+ = 0.037$, $c_- = 0.045$, $p_+ = 0.87$, and $p_- = 3.5$.

Since our interested energy range is as low as 10 GeV, the three-body muon decay contribution to the atmospheric $\nu_\mu$ flux is not negligible, particularly in the near horizontal direction. To obtain this part of contribution, we first compute the atmospheric muon flux from pion and kaon decays. The muon flux induced by pion decays is given by

$$\frac{dN_\mu^\pi(E, \xi, X)}{dE} = \int_{E'}^{\infty} dE_N \int_{E'}^{E_N} dE_\pi \int_0^X dX'' P_\mu(E, X, X'') \times \frac{\Theta(E_\pi - E') \Theta(E'_{r_\pi} - E_\pi)}{d_\pi E_\pi (1 - r_\pi)} \times \int_0^{X''} \frac{dX'}{\lambda_N} P_\pi(E_\pi, X'', X') \frac{1}{E_\pi} F_{N\pi}(E_\pi, E_N) \times \exp\left(-\frac{X'}{\lambda_N}\right) \phi_N(E_N),$$

where $E'$ and $E$ are muon energies at slant depths $X''$ and $X$ respectively, while $P_\mu(E, X, X'')$ is the muon survival probability. The muon flux induced by kaon decays can be calculated in a similar way. Since $\mu^- (\mu^+)$ produced by $\pi^- (\pi^+)$ decays are polarized, we classify muon
flux into four different components such as \( dN_{\nu_R}^{\pi^\pm}/dE \), \( dN_{\nu_R}^{\pi^-}/dE \), \( dN_{\nu_L}^{\pi^+}/dE \), and \( dN_{\nu_L}^{\pi^-}/dE \). We also calculate additional four components of the muon flux arising from the kaon decays. Hence the \( \nu_\mu \) flux arising from muon decays can be written as \( 40, 43 \)

\[
\frac{d^2N_{\nu_\mu}^{\pi^\pm}(E, \xi, X)}{dEdX} = \sum_{s=L,R} \int_{E}^{\infty} dE \frac{F_{\mu_\mu}^{\pi^\pm}(E/E_\mu)}{d\mu(E_\mu, X)/E_\mu}
\]

\[
\times \frac{dN_{\nu_\mu}^{\pi^\pm}(E_\mu, \xi, X)}{dE_\mu},
\]

(14)

where \( d_\mu(E_\mu, X) \) is the muon decay length in units of g/cm\(^2\) at the slant depth \( X \) and \( F_{\mu_\mu}^{\pi^\pm}(E/E_\mu) \) is the normalized decay spectrum of \( \mu_\pm \rightarrow \nu_\mu \). Summing the two-body and three-body decay contributions, we obtain the total intrinsic atmospheric muon neutrino flux. In Fig. 1, we show the comparison of angle-averaged atmospheric muon neutrino flux obtained by our calculation and that obtained by Honda et al. \( 44 \). At \( E_\nu = 10 \text{ GeV} \), two calculations only differ by 3%. At \( E_\nu = 100 \text{ GeV} \), the difference is 10%. We also show in the same figure the atmospheric muon neutrino flux measured by AMANDA-II detector \( 45 \). It is seen that both calculations agree well with AMANDA results.

To completely determine the atmospheric muon neutrino flux, one also needs to calculate the intrinsic atmospheric tau neutrino flux, although this part of contribution is rather small. The intrinsic atmospheric \( \nu_\tau \) flux arises from \( D_s \) decays. This flux can be obtained by solving cascade equations \( 40, 46 \). We obtain

\[
\frac{d^2N_{\nu_\tau}(E, X)}{dEdX} = Z_{ND_s, Z_{D_{s,\nu_\tau}}} \frac{\exp(-X/\Lambda_N)}{\Lambda_N} \phi_N(E_N),
\]

(15)

where \( Z_{NN} \equiv 1 - \lambda_N/\Lambda_N \) and \( Z_{ND_s} \) is a special case of the generic expression

\[
Z_{ij}(E_j) \equiv \int_{E_j}^{\infty} dE_i \frac{\phi_i(E_i)}{\phi_i(E_j)} \frac{\lambda_j(E_j) d\sigma_{iA \rightarrow jY}(E_i, E_j)}{dE_j},
\]

(16)

with \( d\sigma_{iA \rightarrow jY}(E_i, E_j) \equiv d\sigma_{iA \rightarrow jY}(E_i, E_j)/\sigma_i(E_i) \) and \( \lambda_i \) the interaction length of particle \( i \) in units of g/cm\(^2\). The decay moment \( Z_{D_s, \nu_\tau} \) is given by

\[
Z_{D_{s, \nu_\tau}}(E_{\nu_\tau}) \equiv \int_{E_{\nu_\tau}}^{\infty} dE_{D_s} \frac{\phi_{D_s}(E_{D_s})}{\phi_{D_s}(E_{\nu_\tau})} \frac{dD_s(E_{\nu_\tau})}{dD_s(E_{D_s})} F_{D_{s \rightarrow \nu_\tau}}(E_{\nu_\tau}/E_{D_s}),
\]

(17)

where \( d_{D_s} \) is the decay length of \( D_s \) and \( F_{D_{s \rightarrow \nu_\tau}}(E_{\nu_\tau}/E_{D_s}) \) is the normalized decay distribution. In this work, we employ the next-to-leading order (NLO) perturbative QCD \( 47 \) with CTEQ6 parton distribution functions to calculate the differential cross section of \( NA \rightarrow c\bar{c} \) and determine \( Z_{ND_s} \).
Fig. 1: The comparison of angle-averaged atmospheric muon neutrino ($\nu_\mu + \bar{\nu}_\mu$) flux obtained by our calculation and that obtained by Honda et al. [44]. Angle-averaged $\nu_\mu + \bar{\nu}_\mu$ flux from AMANDA-II measurements [45] is also shown.

Finally, the atmospheric $\nu_\mu$ flux taking into account the neutrino oscillation effect is given by

$$\frac{d\bar{N}_{\nu_\mu}(E, \xi)}{dE} = \int dX \left[ \frac{d^2N_{\nu_\tau}}{dE dX} \cdot P_{\nu_\tau \rightarrow \nu_\mu} ight. \left. + \frac{d^2N_{\nu_\mu}}{dE dX} \cdot \left( 1 - P_{\nu_\mu \rightarrow \nu_\tau} \right) \right],$$

(18)

where $P_{\nu_\mu \rightarrow \nu_\tau} (E, L(X, \xi)) = P_{\nu_\tau \rightarrow \nu_\mu} (E, L(X, \xi)) \equiv \sin^2 2\theta_{23} \sin^2 (1.27 \Delta m^2_{31} L/E)$ is the $\nu_\mu \rightarrow \nu_\tau$ oscillation probability and $L(X, \xi)$ is the linear distance from the neutrino production point to the position of IceCube DeepCore array. The unit of $\Delta m^2_{31}$ is eV$^2$ while $L$ and $E$ are in units of km and GeV respectively. The best-fit values for oscillation parameters obtained from a recent analysis [48] are $\Delta m^2_{31} = 2.47 \cdot 10^{-3}$ eV$^2$ and $\sin^2 2\theta_{23} = 1$ respectively.
IV. RESULTS

In IceCube DeepCore, the event rate for contained muons is given by

\[
\Gamma_\mu = \int_{E_{\mu}^{th}}^{E_{\mu}^{max}} dE_\mu \int_{E_{\mu}^{th}}^{E_{\nu_\mu}^{max}} dE_{\nu_\mu} N_A \rho_{ice} V_{tr} \\
\times \frac{d\Phi_{\nu_\mu}}{dE_{\nu_\mu}} \cdot \frac{d\sigma_{CC_{\nu N}}(E_{\nu_\mu}, E_\mu)}{dE_\mu} + (\nu \rightarrow \bar{\nu}),
\]

(19)

where \(\rho_{ice} = 0.9 \text{ g cm}^{-3}\) is the density of ice, \(N_A = 6.022 \times 10^{23} \text{ g}^{-1}\) is Avogadro’s number, \(V_{tr} \approx 0.04 \text{ km}^3\) is the effective volume of IceCube DeepCore array for muon track events \([25]\), \(d\Phi_{\nu_\mu}/dE_{\nu_\mu}\) is the muon neutrino flux arrived at IceCube, \(E_{\mu}^{max}\) is taken as \(m_\chi\) for annihilation and \(m_\chi/2\) for decay, and \(E_{\mu}^{th}\) is the threshold energy for muon track events. In this work, we use differential cross sections \(d\sigma_{CC_{\nu N}}(E_{\nu_\mu}, E_\mu)/dE_\mu\) given by Ref. \([49]\) with CTEQ6 parton distribution functions. We also set \(E_{\mu}^{th} = 10 \text{ GeV}\).

As stated before, we consider neutrino fluxes generated by the annihilation channels \(\chi\chi \rightarrow b\bar{b}, \tau^+\tau^-,\) and \(\mu^+\mu^-\), and the decay channels \(\chi \rightarrow b\bar{b}, \tau^+\tau^-\) and \(\mu^+\mu^-\). Given the atmospheric neutrino background, we present in Fig. 2 the required DM annihilation cross section as a function of \(m_\chi\) for threshold energy \(E_{\mu}^{th} = 10 \text{ GeV}\) and a cone half-angle \(\psi_{max} = 1^\circ\) such that the neutrino signature from DM annihilations can be detected at the 2\(\sigma\) significance in five years. Non-detection of such a signature would then exclude the parameter region above the curve at the 2\(\sigma\) level. We have presented results corresponding to different annihilation channels. One can see that the required annihilation cross section for 2\(\sigma\) detection significance is smallest for \(\chi\chi \rightarrow \mu^+\mu^-\) channel and largest for the channel \(\chi\chi \rightarrow b\bar{b}\). We also present the 3\(\sigma\) constraint on \(\chi\chi \rightarrow \tau^+\tau^-\) annihilation cross section obtained from Super-Kamiokande data of upward going muons \([18]\), which has been used to rule out WIMP annihilations into \(\tau^+\tau^-\) as a possible source of previously mentioned \(e^\pm\) anomalies \([18, 20]\). Such a constraint can be compared with the expected 2\(\sigma\) constraint on the same annihilation channel from DeepCore detector.

Constraints on DM annihilation cross section were also obtained from gamma ray observations and cosmology. H.E.S.S. telescope performed a search for the very-high-energy (\(\geq 100 \text{ GeV}\)) \(\gamma\)-ray signal from DM annihilations over a circular region of radius 1\(^\circ\) centered at the GC \([50]\). With DM particles assumed to annihilate into \(q\bar{q}\) pairs, the limit on DM annihilation cross section as a function of \(m_\chi\) for NFW DM density profile is derived in Ref. \([50]\). We present this constraint in Fig. 2 as well. For \(m_\chi > 300 \text{ GeV}\), the parame-
Fig. 2: The dashed line, thin solid line, and dot-dashed lines are the expected constraints on DM annihilation cross section by DeepCore detector for \( \chi \chi \rightarrow b \bar{b} \), \( \chi \chi \rightarrow \mu^+ \mu^- \), and \( \chi \chi \rightarrow \tau^+ \tau^- \) channels, respectively. The thick solid line is the H.E.S.S constraint on the annihilation cross section of DM into the light quark pair \( \chi \chi \rightarrow q \bar{q} \) \[50\]. The dot-dot-dashed line is the constraint on \( \chi \chi \rightarrow e^+ e^- \) annihilation cross section from the analysis of cosmic microwave background (CMB) data \[51\]. The dotted line is the 3\( \sigma \) constraint on the annihilation cross section of \( \chi \chi \rightarrow \tau^+ \tau^- \) from Super-Kamiokande data \[18\].

In the parameter space with \( B > 100 \) (i.e., \( \langle \sigma v \rangle > 3 \times 10^{-24} \text{m}^3 \text{s}^{-1} \)) in Fig. 2 could be excluded by the H.E.S.S. data. However, the H.E.S.S. constraint on \( \chi \chi \rightarrow q \bar{q} \) becomes much weaker for \( m_\chi < 300 \) GeV. We point out that this constraint is obtained with NFW profile normalized at \( \rho_\odot = 0.39 \) GeVcm\(^{-3}\). The H.E.S.S. constraint would be slightly less stringent if our adopted normalization \( \rho_\odot = 0.3 \) GeVcm\(^{-3}\) is used.

Cosmological Constraints on DM annihilation cross section can be obtained from the data of big-bang nucleosynthesis (BBN) and cosmic microwave background (CMB). In such an analysis, the DM annihilation cross section is assumed to be velocity dependent such that
where $v_0$ is the DM velocity at the freeze-out temperature, while the values for $\epsilon$ and $n$ depend on specific models. For Sommerfeld enhancement of the DM annihilation cross section induced by light-scalar exchange, one has $n = 1$ and $\epsilon \simeq m_\phi/m_\chi$ with $m_\phi$ the light-scalar mass. The CMB anisotropy can be affected by the energy injection in the recombination epoch due to DM annihilation process such as $\chi\chi \rightarrow e^+e^-$ and $\chi\chi \rightarrow W^+W^-$. In Fig. 2, we show the upper bound on $\langle \sigma v \rangle$ for $\chi\chi \rightarrow e^+e^-$ channel for $n = 1$ and $T_{KD} = 1$ MeV with $T_{KD}$ the kinetic decoupling temperature. This upper bound is inferred from the upper bound on $\langle \sigma v \rangle_0$ such that the resulting CMB power spectrum remains consistent with observations. The above upper bound on $\langle \sigma v \rangle_0$ is shown to be sensitive to the parameter $\epsilon$ while the corresponding bound on $\langle \sigma v \rangle$ is insensitive to it. It will be interesting to convert the above
bound on $\langle \sigma (\chi \chi \rightarrow e^+e^-)v \rangle$ into the one on $\langle \sigma (\chi \chi \rightarrow \mu^+\mu^-)v \rangle$. However such a conversion is highly model dependent which is beyond the scope of the current work.

Having compared the expected sensitivities of DeepCore detector with other experimental constraints on various DM annihilation channels, we discuss how the DeepCore constraint on DM annihilation cross section varies with the chosen cone half-angle and threshold energy. We use the channel $\chi \chi \rightarrow \mu^+\mu^-$ to illustrate these effects. Fig. 3 shows the required DM annihilation cross section $\langle \sigma (\chi \chi \rightarrow \mu^+\mu^-)v \rangle$ for a 2$\sigma$ detection in five years for different cone half-angle $\psi_{\text{max}}$. One can see that the constraint on the DM annihilation cross section gets stronger as $\psi_{\text{max}}$ increases from 1° to 2°. However, the constraint turns weaker as $\psi_{\text{max}}$ increases further. This is due to the factor $J_2(\Delta\Omega)\Delta\Omega$ which depends on the square of DM density (see Eq. (4)). The constraint curve rises with an increasing $\psi_{\text{max}}$ for $\psi_{\text{max}} > 2^\circ$, since the signal increases slower than the background does for such a $\psi_{\text{max}}$ range. In this figure, we also show the result for a higher threshold energy $E_{\mu}^{\text{th}} = 50$ GeV with a cone half-angle $\psi_{\text{max}} = 10^\circ$ for comparison. This result is taken from Ref. [28] where $\psi_{\text{max}} = 10^\circ$ is identified as the most optimal cone half-angle for constraining DM annihilation cross section at that threshold energy. We note that, for large $m_\chi$, lowering $E_{\mu}^{\text{th}}$ from 50 GeV to 10 GeV results in more enhancement on the event rate of atmospheric background than that of DM annihilation. Hence, the constraint on DM annihilation cross section is weaker by choosing $E_{\mu}^{\text{th}} = 10$ GeV. On the other hand, for small $m_\chi$, lowering $E_{\mu}^{\text{th}}$ enhances more on the event rate of DM annihilations than that of atmospheric background. For $m_\chi < 100$ GeV, one can see that the constraint on DM annihilation cross section with $E_{\mu}^{\text{th}} = 10$ GeV is always stronger than that with $E_{\mu}^{\text{th}} = 50$ GeV. We note that DeepCore constraints on other annihilation channels have similar cone half-angle and threshold energy dependencies.

Besides studying DeepCore constraints on DM annihilation channels, we also present constraints on DM decay time for $\chi \rightarrow b\bar{b}$, $\tau^+\tau^-$ and $\mu^+\mu^-$ channels. Fig. 4 shows the required DM decay time for a 2$\sigma$ detection of neutrino signature in five years for each channel. We have taken $E_{\mu}^{\text{th}} = 10$ GeV and $\psi_{\text{max}} = 90^\circ$. Non-detection of such a signature would then exclude the parameter region below the curve at the 2$\sigma$ level. For comparison, we also show 3$\sigma$ limit on $\chi \rightarrow \tau^+\tau^-$ from Super-Kamiokande data of upward going muons [18]. One can see that the channel $\chi \rightarrow \mu^+\mu^-$ requires the smallest decay width to reach the 2$\sigma$ detection significance in five years of DeepCore data taking.

Finally we present how the DeepCore constraint on DM decay time varies with the
Fig. 4: The dot-dashed line, solid line and dotted line are the required DM decay time for a 2σ detection of neutrino signature in five years for \( \chi \rightarrow b \bar{b} \), \( \mu^+\mu^- \) and \( \tau^+\tau^- \) channels, respectively. The dashed line is the Super-Kamiokande constraint on \( \chi \rightarrow \tau^+\tau^- \) \([18]\).

chosen cone half-angle and threshold energy. We use the channel \( \chi \rightarrow \mu^+\mu^- \) to illustrate these effects. Fig. 5 shows the required DM decay time \( (\chi \rightarrow \mu^+\mu^-) \) as a function of \( m_\chi \) for different cone half-angle \( \psi_{\text{max}} \) such that the neutrino signature from DM decays can be detected at the 2σ significance in five years. For DM decays, the curve rises with increasing \( \psi_{\text{max}} \) since the event rate of DM signal increases faster than that of atmospheric background as \( \psi_{\text{max}} \) increases. For comparison, we show the required DM decay time for a 2σ detection in five years with \( E_{\mu}^{\text{th}} = 50 \) GeV and \( \psi_{\text{max}} = 50^\circ \). It has been pointed out in Ref. \([28]\) that \( \psi_{\text{max}} = 50^\circ \) gives the most stringent constraint on DM decay time for \( E_{\mu}^{\text{th}} = 50 \) GeV. One can see that the constraint on DM decay time is strengthened by lowering \( E_{\mu}^{\text{th}} \) from 50 GeV to 10 GeV for \( m_\chi < 300 \) GeV.
Fig. 5: The required DM decay time ($\chi \rightarrow \mu^+\mu^-$) as a function of $m_\chi$ such that the neutrino signature from DM decays can be detected at the $2\sigma$ significance in five years. Results corresponding to different $\psi_{\text{max}}$ are presented. For comparison, we also show the result with $E_{\mu}^{\text{th}} = 50$ GeV and $\psi_{\text{max}} = 50^\circ$ [28].

V. SUMMARY

We have calculated the track event rate in IceCube DeepCore array resulting from muon neutrino flux produced by annihilations and decays of dark matter in the galactic halo. In this calculation, we have employed NFW profile for dark matter mass distribution and consider the channels $\chi\chi \rightarrow b\bar{b}$, $\tau^+\tau^-$, and $\mu^+\mu^-$ for annihilations and the channels $\chi \rightarrow b\bar{b}$, $\tau^+\tau^-$ and $\mu^+\mu^-$ for decays. We also calculated the track event rate due to atmospheric background. We compare the signal event rate with that of the background for $E_\mu \geq 10$ GeV.

We have presented sensitivities of IceCube DeepCore array to neutrino flux arising from dark matter annihilations and decays. For a given dark matter mass, we evaluated the dark matter annihilation cross section and dark matter decay time such that a $2\sigma$ detection
significance for the above signatures can be achieved by DeepCore array for a five-year data taking. The DeepCore sensitivities on dark matter annihilation cross section were compared with the constraint obtained from H.E.S.S. gamma ray observations and the constraint derived from the data of CMB power spectrum. Using $\chi\chi \rightarrow \mu^+\mu^-$ and $\chi \rightarrow \mu^+\mu^-$ as examples, we also presented how DeepCore constraints on dark matter annihilation cross section and dark matter decay time vary with the chosen cone half-angle and threshold energy. We like to point out that our calculated sensitivities based upon $E^{th}_\mu = 10$ GeV are significantly more stringent than those obtained by taking $E^{th}_\mu = 50$ GeV for $m_\chi < 100$ GeV in the annihilation channel and $m_\chi < 300$ GeV in the decay channel.
