Unified formal reduction for fluid models of free-surface shallow gravity-flows

François Bouchut * Sébastien Boyaval †

May 7, 2014

Abstract

We propose a unified approach to the formal long-wave reduction of several fluid models for thin-layer incompressible homogeneous flows driven by a constant external force like gravity. The procedure is based on a mathematical coherence property that univocally defines one reduced model given one rheology and one thin-layer regime. For the first time, as far as we know, various known reduced models can thus be investigated within a single mathematical framework, for various rheologies (viscous and viscoelastic) and various limit regimes (fast inertial flows and slow viscous flows). Furthermore, our systematic procedure also produces new reduced models for viscoelastic non-Newtonian fluids and improves on our previous work [Bouchut & Boyaval, M3AS (23) 8, 2013].

1 Introduction

Formal a priori simplifications of a model is a game physicists and mathematicians have been playing for years, in particular for fluid equations. Historically, reduced models indeed proved useful because they were more amenable to analytical (exact) solution than full models, for instance the Saint-Venant equations, and thus helped understand a few simple phenomena (e.g. dam breaks) in a time where computer simulations did not exist. Nowadays, reduced models are still sometimes preferred to full models, for instance to numerically simulate cheaply complex fluid flows, and next discriminate against various possible rheologies by comparison with experiments. In this work, we have more precisely in mind paving the way for a better modelling of the rheology in e.g. mud flows and landslides, which are still much investigated, by experimentalists in particular [4]. Indeed, their thin-layer geometry apparently suits well with simplifications, see e.g. [5].

Numerous reduced models have already been derived for gravity-driven free-surface shallow flows with various rheologies in various regimes, however they are still difficult to connect one another. A unifying viewpoint of various surface wave models for water (Newtonian) flows has been constructed recently [17], but it holds only for purely-irrotational water flow models. A generic mathematically-inclined derivation procedure for slow flows close to a stationary solution has also been used recently for various rheologies, see e.g. [23, 29], but it holds only for viscous (laminar) flow regimes. Our primary goal here is to establish another mathematically-inclined framework, that is common to various thin-layer flows (slow/fast) and several fluids (Newtonian/non-Newtonian).

To this aim, we introduce a procedure that yields various long-wave reduced models when using various rheologies with Navier-Stokes equations depending on various thin-layer flow regimes.

Our procedure, inspired by [31, 36] where the viscous shallow water equations are derived (see Section 3), is based on a very natural mathematical coherence property. Although it cannot certify rigorously when and how a solution to the reduced model is a good approximation of a solution to the full model, our formal procedure is univoque at least: it delivers a single reduced model given one rheology and one thin-layer long-wave flow regime, whose solution should approximately solve the original full model provided the assumptions used for the derivation hold.

We obtain a synthetic viewpoint of various possible simplifications of the Navier-Stokes equations modelling a fluid under gravity in a free-surface thin-layer geometry, when the rheology varies (that is, the modelling of the internal stresses), as well as when the scaling assumptions for the flow regime vary (i.e. in the momentum equation, the hydrostatic forces are mainly balanced by the purely kinematic hydrodynamic forces in fast inertial flows, as opposed to the internal stresses in slow viscous flows).

We also obtain new reduced models for fluids with complex rheologies.

- For viscous Newtonian fluids (modelled by the standard Navier-Stokes equations), we obtain either viscous shallow water equations in inertial regimes (as e.g. in [31, 36]) or lubrication equations in viscous regimes (as e.g. in [41, 23, 26]), in Section 4.

- For viscous non-Newtonian fluids (nonlinear power-law models), we obtain either a nonlinear version of the shallow water equations in inertial regimes that is apparently new, or nonlinear lubrication equations in viscous regimes (see [29] and references therein), in Section 5.

- For viscoelastic non-Newtonian fluids, we obtain either shallow water equations with additional stress terms which extends the recent work [18] in inertial regimes, or new lubrication equations in viscous regimes (different than those in [24, 25]), in Section 6.

A few remarks are also in order.
• The case of perfect fluids (no internal stresses) is singular, and it seems one cannot naturally derive a closed reduced model without coming back to an assumption about the dissipation terms initially neglected: we treat it as the inviscid limit of the viscous Newtonian case.

• The case of some viscoplastic Non-Newtonian fluids (i.e. some Bingham fluids) occurs as a singular limit of the nonlinear power-law models. Now, this case is interesting from the modelling viewpoint (some plastic non-Newtonian fluids are believed to possess a yield-stress that seems to suit well for modelling transitions of fluid-solid type like e.g. in avalanches), but already difficult from the mathematical viewpoint (the model is undetermined below the yield-stress) as well as from the physical viewpoint (the existence of a yield-stress to account for a transition of the fluid-solid type is still much debated). That is why it is in fact the single fluid model with plasticity that we investigate here. Our framework could nevertheless serve as a basis for future thin-layer investigations of models taking into account transitions of fluid-solid type, the modelling of viscoplasticity still being in its infancy.

• Concerning viscoelastic fluids, we improve here the model derived in [18] from simple constitutive equations (only linear in the tensor state variable “conformation” that accounts for viscoelasticity, though already physically-consistent from the frame-invariance viewpoint) in the sense that here, we take into account friction at the bottom, surface tension, two-dimensional effects and a purely Newtonian additional viscosity.

For a recent physically-inclined review of thin-film flows, we recommend [20], and [41] for an older one with a focus on stability. Let us now mathematically set the problem.

2 Mathematical setting of the problem

We endow the space \( \mathbb{R}^3 \) with a Galilean reference frame using cartesian coordinates \((e_x, e_y, e_z)\). We denote by \( a_x \) (respectively \( a_y, a_z \)) the component in direction \( e_x \) (resp. \( e_y, e_z \)) of a vector (that is a rank-1 tensor) \( a \), by \( a_{xz}, a_{yz}, \ldots \) the components of higher-rank tensors, by \( a_H \) the vector of “horizontal” components \((a_x, a_y)\), by \( (a_H)^\perp = (-a_y, a_x) \) an orthogonal vector, by \( \nabla_H a \) the horizontal gradient \((\partial_x a, \partial_y a)\) of a smooth function \( a : (x, y) \to a(x, y) \), and by \( D_t a \) the material time-derivative \( \partial_t a + (u \cdot \nabla) a \). We use the Frobenius norm \( |a| = \text{tr}(a^T a)^{1/2} \) for a 2-tensor.

Gravity flows of incompressible homogeneous fluids are governed by Navier-Stokes equations

\[
\begin{aligned}
D_t u &= \text{div}(S) + f \quad \text{in } \mathcal{D}(t), \\
\text{div } u &= 0 \quad \text{in } \mathcal{D}(t),
\end{aligned}
\]
on a regional scale where gravity is the single external force \( f \), with the velocity field \( u \) as unknown variable plus Cauchy stress tensor \( S = -pI + T \) (\( T \) is the deviatoric part of \( S \) when \( \text{tr}(T) = 0 \)).

We consider cases where the fluid is contained for all times \( t \geq 0 \) within a cylindrical domain

\[
\mathcal{D}(t) = \{ x = (x, y, z) , \ (x, y) \in \Omega_0 , 0 < z - b(x, y) < h(t, x, y) \},
\]

with a free surface \( z = b(x, y) + h(t, x, y) \) (a simplified modelling for a liquid-gas interface). The free surface and the bottom topography \( z = b(x, y) \) are thus unfolded (i.e. single-valued) two-dimensional parametrized manifolds. Furthermore, we are more specifically interested in the case of shallow flows where the two manifolds are assumed close to one-another in the “vertical” direction \( e_z \) – whatever the “horizontal” position \( (x, y) \in \Omega_0 \) – in comparison with a characteristic horizontal length \( L \), and where they a priori never touch (though one usually next extends the application of the model to cases with vacuum). We write this assumption

\[
h \sim \varepsilon
\]

using an adimensional small parameter \( \varepsilon \geq 0 \). It means that \( h/(\varepsilon L) \) is bounded above and below independently of \( (x, y) \in \Omega_0 , t \geq 0 \) as \( \varepsilon \to 0 \), as opposed to \( a = O(\varepsilon) \) for a variable \( a \), which simply means that the adimensional quantity \( a/(\varepsilon A) \) (where \( A \) is the natural characteristic size of \( a \) as a function of \( L, T \), see below) is bounded above, and may in fact decay faster than \( \varepsilon \) to zero as \( \varepsilon \to 0 \). Note that we shall also use componentwise notation, e.g. \( a_1, a_2 = O(\varepsilon^{\alpha_1}, \varepsilon^{\alpha_2}) \) for \( a_1 = O(\varepsilon^{\alpha_1}) \) and \( a_2 = O(\varepsilon^{\alpha_2}) \).

The goal of this work is to derive a closed system of approximate equations for the flow that hopefully define a simpler and useful (that is, physically meaningful) mathematical model than (1) in the vicinity of the limit \( \varepsilon \to 0 \). Note that we limit to cases where \( \nabla H h = O(\varepsilon) \) holds, so that the reduced model captures only long-wave oscillations of the free surface.

Of course, at this stage, the system of equations (1) is not closed. One still need to specify the rheology of the fluid (that is, invoke other equations linking \( S \) with \( u \)) as well as boundary conditions. We recall that it is exactly the goal of this work to derive approximations of (1) for various rheologies and flow regimes using the same procedure, thereby defining a common framework to compare rheological models with experimental measures through simple reduced models in the case of free-surface thin-layer flows. We have in mind rheological models for:

- viscous Newtonian fluids like water, such that the deviatoric stress tensor is a linear function of the rate-of-strain tensor \( D(u) = \frac{1}{2}(\nabla u + \nabla u^T) \), hence \( T = 2\eta_s D(u) \), with \( \eta_s \) a constant kinematic viscosity,
- viscous non-Newtonian fluids, what most complex fluids are in a small range of shear rates at least, such that the mechanical behaviour is still described with a purely viscous deviatoric stress tensor, but using a non-linear power-law \( T = 2\eta_s |D(u)|^{n-1} D(u) \) (termed pseudoplastic or shear-thinning if \( 0 < n < 1 \), dilatant or shear-thickening if \( n > 1 \)) for viscosity,
• viscoelastic non-Newtonian fluids like polymer solutions, such that $T = 2\eta_s D(u) + \tau$ invokes a non-Newtonian extra-stress $\tau$ that is not necessarily deviatoric and defined through supplementary (integro-)differential equations.

Note that there is a huge amount of non-Newtonian models in the literature [6].

• Interestingly, the nonlinear power-law models for viscous non-Newtonian fluids coincide with the standard Navier-Stokes equations for viscous Newtonian fluids when $n = 1$ and with a Bingham model for viscoplastic fluids when $n = 0$. Although stress is undetermined in Bingham model when $|D(u)| = 0 \Leftrightarrow |T| < 2\eta_s$, Bingham model can be understood as the limit of a regularized model [28] and remains the least disputed basic model for the still much debated viscoplastic non-Newtonian fluids.

• Viscoelastic fluid models have been used successfully for the accurate description of polymer solutions for instance, see e.g. [15, 16]. We repeat that we shall be content here with simple prototypical models among the numerous possibilities (see Section [6]).

We believe that the various prototypical rheologies mentioned above are representative enough to define a first common mathematical framework for various shallow flows with various rheologies. We now complement them with the following common boundary conditions (BCs).

Let us denote by $n : (x, y) \in \Omega_0 \rightarrow n(x, y)$ the unit vector of the direction normal to the bottom

$$n = \left( \frac{-\nabla_H b}{\sqrt{1 + |\nabla_H b|^2}} \right)$$

(inward the fluid) and by $(N_t, N)$ the time-space normal at the free surface (outward the fluid)

$$N_t = -\partial_t (b+h)/\sqrt{1 + |\nabla_H (b+h)|^2} \quad N = \left( \frac{-\nabla_H (b+h)}{1} \right) / \sqrt{1 + |\nabla_H (b+h)|^2}.$$  

An orthonormal frame is defined locally everywhere on the bottom using as basis in tangent planes

$$t_1 = \left( \frac{(\nabla_H b)^T}{|\nabla_H b|} \right) / |\nabla_H b| \quad t_2 = \left( \frac{-\nabla_H b}{-|\nabla_H b|^2} \right) / (|\nabla_H b| \sqrt{1 + |\nabla_H b|^2})$$

when $|\nabla_H b| \neq 0$, otherwise $t_1 = (0, -1, 0)^T$, $t_2 = (-1, 0, 0)^T$. We require, at the bottom of the fluid, no penetration in the normal direction

$$u \cdot n = 0, \quad \text{for} \ z = b(x, y), \ (x, y) \in \Omega_0,$$

and a Navier friction dynamic condition with coefficient $k$ in the tangent plane

$$S n \wedge n = k u \wedge n, \quad \text{for} \ z = b(x, y), \ (x, y) \in \Omega_0;$$
at the free surface, the usual kinematic condition $N_t + N \cdot u = 0$, i.e.
(8) 
$$-\partial_t (b + h) - u_x \partial_x (b + h) - u_y \partial_y (b + h) + u_z = 0, \quad \text{for } z = b(x, y) + h(t, x, y), \ (x, y) \in \Omega_0,$$
and surface tension with coefficient $\gamma$ as dynamic condition
(9) 
$$SN = \gamma \kappa N, \quad \text{for } z = b(x, y) + h(t, x, y), \ (x, y) \in \Omega_0,$$
where $\kappa(t, x, y) = -\text{div} \ N(t, x, y)$ is the (local) mean curvature at $z = b(x, y) + h(t, x, y), \ (x, y) \in \Omega_0$; and finally, at the lateral boundary $\{x = (x, y, z), \ (x, y) \in \partial \Omega_0, 0 \leq z - b(x, y) \leq h(t, x, y)\}$, inflow/outflow or periodic boundary conditions (for example).

Note that the question of existence and uniqueness of solutions to the Boundary Value Problem (BVP) above is difficult and precisely answered only in a few specific situations, for instance see $[1, 3, 13, 43]$ for Newtonian viscous fluids and $[38]$ for non-Newtonian fluids. In this work, we simply assume the boundary conditions as above (plus initial conditions) allows one to precisely determine one solution (at least) to the bulk equations. On the other hand, the fact that we restrict to reduced models that only capture long-wave oscillations of the free surface is also an implicit assumption about the regularity of the solutions to our models (reduced or not).

In the next sections, it will be possible to derive simplified equations that are verified by (univoque) approximations of the solutions to the BVP above in the limit $\varepsilon \to 0$ only over fixed time ranges $T$, of course. Then, for the sake of clarity, we rewrite the system of equations using adimensional variables that are functions of the non-dimensional scaled coordinates $(\tilde{t}, \tilde{x}, \tilde{y}, \tilde{z}) = (t/T, x/L, y/L, z/L)$, which we next abusively still write $(t, x, y, z)$. On noting that $p$ and $T$ both have the dimension $(L/T)^2$, we normalize the gravity constant as $gT^2/L$ and obtain adimensional bulk equations which we abusively still write
(10) 
$$\begin{align*}
D_t u &= -\nabla p + \sum_{i=x,y,z} (\partial_x T_{ix} + \partial_y T_{iy} + \partial_z T_{iz}) e_i - f, \\
\text{div} \ u &= 0,
\end{align*}$$
without tilde, and that are complemented with the boundary conditions
(11a) 
$$(u_H \cdot \nabla_H) b = u_z, \quad \text{for } z = b(x, y),$$
(11b) 
$$T n - ((T n) \cdot n) n - k(u - (u \cdot n)n) = 0, \quad \text{for } z = b(x, y),$$
(11c) 
$$\partial_t h + (u_H \cdot \nabla_H)(b + h) = u_z, \quad \text{for } z = b(x, y) + h(t, x, y),$$
(11d) 
$$-pN + T N + \gamma \text{div}(N)N = 0, \quad \text{for } z = b(x, y) + h(t, x, y),$$
where $k$ and $\gamma$ have been scaled by $L/T$ and $L^3/T^2$ respectively.

We obtain simplified equations by successive approximations of the solutions to (10–11a–11b–11c–11d) following $[31, 36]$, first for generic Navier-Stokes equations in Section 3 then specifically for many rheologies in various limit
regimes in Sections 4 (Newtonian fluids), 5 (power-law fluids) and 6 (Oldroyd-B fluids). Solutions to those simplified equations shall indeed (formally) approximate solutions to (10–11a–11b–11c–11d) insofar as they satisfy the full system of equations plus small error terms.

3 A generic long-wave thin-layer framework for free-surface gravity flows

A usual assumption to formally reduce the thin-layer flow equations for long-wave oscillations of the free-surface is small topography variations. Extensions to the case of an arbitrary topography are nontrivial, see e.g. [19]. We thus nextcontent ourself with the quite general case of a topography slowly varying around a plane inclined by a constant angle $\Theta$. More precisely, we choose in (10)

$$f = (f_x \equiv +g \sin \Theta, f_y \equiv 0, f_z \equiv -g \cos \Theta)$$

(Navier-Stokes equations are Galilean frame-invariant and rotation is a Galilean change of frame) and we assume

$$\nabla_H b = O(\varepsilon).$$

It is also natural to assume bounded horizontal velocities $u_H = O(1)$, at $z = b + h$ in particular, and $\text{div}_H u_H = O(1)$. Successive implications can next be “naturally” derived following a procedure similar to that in [31, 36], up to the introduction of an additional assumption (i.e. $k u_H|_{z=b} = O(\varepsilon)$).

1. We consider first the mass continuity equation $\text{div} u = 0$ with BC (11a)

$$u_z = u_H|_{z=b} \cdot \nabla_H b - \int_b^z \text{div}_H u_H.$$

Using $u_H = O(1)$ at $z = b$, this yields $u_z = O(\varepsilon)$, and $\nabla_H h = O(\varepsilon)$ by (11c). In fact, assuming that only long-wave oscillations of the free surface matter at first order in $\varepsilon$, i.e. $\nabla_H h = O(\varepsilon)$, is equivalent to $u_z = O(\varepsilon)$ as long as (H1) holds, by the formula $u_z = u_H|_{z=b+h} \cdot \nabla_H (b + h) + \partial_t h + \int_{b+h}^{z} \text{div}_H u_H$ combining (11c) and $\text{div} u = 0$.

Reciprocally, the mass continuity equation and the BCs (11a,11c) are satisfied up to error terms of order $O(\varepsilon^{a,a+1,a+1})$, respectively (with $a > 0$), if $h, u_z, u_H$ are replaced with approximations up to error terms of order $O(\varepsilon^{a+1,a+1,a})$, respectively (recall $h \sim \varepsilon$), provided of course $\text{div}_H u_H$ and $\partial_t h$ are also approximated up to $O(\varepsilon^a)$ and $O(\varepsilon^{a+1})$ (like $u_H$ and $h$).

2. Second, using $u_z = O(\varepsilon)$, one infers from the momentum equation projected along $e_z$ that

$$\partial_z p = f_z + (\partial_z T_{zz} + \text{div}_H T_{Hz}) + O(\varepsilon)$$

Unified derivation of reduced models for shallow flows
must be satisfied by \( p, T_{zz}, T_{Hz} \), as well as by approximations of \( p, T_{zz}, T_{Hz} \) up to errors \( O(\varepsilon^{2,1}) \), respectively (assuming \( \partial_z p, \partial_z T_{zz}, \text{div}_H T_{Hz} \) are approximated up to \( O(\varepsilon^{1,1}) \)).

Moreover, using \( \nabla_H h = O(\varepsilon) \) and \( \nabla_H b = O(\varepsilon) \), one infers \( \text{div} \, N(t, x, y) = -\Delta_H (b + h) + O(\varepsilon^3) \), so the BC (11d) rewrites (recall \( \gamma \sim 1 \) is a constant)

\[
\frac{\partial}{\partial t} (p)_{|z=b+h} = -\gamma \Delta_H (b + h) + (T_{zz} - T_{Hz} \cdot \nabla_H (b + h)) + O(\varepsilon^3)
\]

which is satisfied as well by approximations of \( h, p, T \) up to errors of order \( O(\varepsilon^{3,3,3,2}) \) (at \( z = b + h \) at least for \( p, T_{zz}, T_{Hz} \), provided \( \Delta_H h, \nabla_H h \) are approximated as well as \( h \)).

Since (14) still holds with \( O(\varepsilon^3) \) replaced by \( O(\varepsilon^2) \), one can use (14) consistently with (13) in order to obtain (after integration)

\[
(15) \quad p = f_z (z - (b + h)) - \gamma \Delta_H (b + h) + T_{zz} - \text{div}_H \int_z^{b+h} T_{Hz} + O(\varepsilon^2).
\]

Like (13), (14) with \( O(\varepsilon^3) \) replaced by \( O(\varepsilon^2) \) and (15) are satisfied by approximations of \( p, T_{zz}, T_{Hz} \) up to errors of order \( O(\varepsilon^{2,1}) \), and an approximation of \( h \) up to \( O(\varepsilon^2) \), which in turn requires approximations of \( u_z, u_H \) up to errors of order \( O(\varepsilon^{2,1}) \) (recall the first item).

3. Third, it is natural to assume \( \Delta_H (b + h) = \text{div}_H (\nabla_H b + \nabla_H h) = O(\varepsilon) \) on the one hand, and \( \max(T_{Hz}, T_{zz}, T_{Hz})_{|z=b+h} = O(1) \) on the other hand. One then gets

\[
(16) \quad T_{Hz}|_{z=b+h} = (T_{Hz} - T_{zz} I) \nabla_H (b + h) + O(\varepsilon^2)
\]

from BC (11d) with (14) (even with \( O(\varepsilon^3) \) replaced by \( O(\varepsilon^2) \) in (14)) plus the scaling

\[
(17) \quad T_{Hz}|_{z=b+h} = O(\varepsilon).
\]

Moreover, from (11b) and \( \nabla_H b = O(\varepsilon) \), we get at \( z = b \) using (5)

\[
T_{Hz} \cdot (\nabla_H b)^\perp - (\nabla_H b)^\perp \cdot T_{Hz} \nabla_H b
= ku_H \cdot (\nabla_H b)^\perp (1 + O(\varepsilon^2)),
\]

\[
(1 - O(\varepsilon^2)) T_{Hz} \cdot \nabla_H b - \nabla_H b \cdot T_{Hz} \nabla_H b + |\nabla_H b|^2 T_{zz}
= ku_H \cdot \nabla_H b + u_z |\nabla_H b|^2 (1 + O(\varepsilon^2)),
\]

thus one obtains, with (11a) and, if \( \nabla_H b \neq 0 \),

\[
T_{Hz} = \frac{T_{Hz} \cdot \nabla_H b}{|\nabla_H b|^2} \nabla_H b + \frac{T_{Hz} \cdot (\nabla_H b)^\perp}{|\nabla_H b|^2} (\nabla_H b)^\perp,
\]

(18) \( T_{Hz}|_{z=b} = (T_{Hz} - T_{zz} I) \nabla_H b + ku_H (1 + O(\varepsilon^2)) + |T_{Hz}| O(\varepsilon^2) \).
Unified derivation of reduced models for shallow flows

If \( \nabla_H b = 0 \), \( T_{Hz}|_{z=b} = ku_H \) straightforwardly follows from (11b), so (18) remains true.

To proceed, although assuming \( \max(T_H H, T_{zz}, T_{Hz})|_{z=b} = O(1) \) seems natural, it is clear that one shall also need an assumption for the scaling of \( ku_H|_{z=b} \), which is less natural.

Note already that the approximations (16–18) of the BCs (11d, 11b) are also satisfied by approximations of \( T_{HH}, T_{zz}, T_{Hz} \) up to error terms of order \( O(\varepsilon^{1,1,2}) \) at least at \( z = b + h \), as long as (14) holds (possibly with \( O(\varepsilon^3) \) replaced by \( O(\varepsilon^2) \)) and \( ku_H|_{z=b} \) is approximated up to an error \( O(\varepsilon^2) \). At this stage, this is in contrast with (13) which requires approximations of \( T_{zz}, T_{Hz} \) up to \( O(\varepsilon^{2,1}) \). But recall that \( T \) is still to be connected to the other unknown variables through additional equations once we will have fixed the rheology of the fluid. In fact, most of the work in the sequel will consist in deriving approximations of the stresses that are coherent with approximations of the other variables. (Anticipating the case of Newtonian fluids, we shall for instance be able to use approximations of \( T_{HH}, T_{zz}, T_{Hz} \) up to \( O(\varepsilon^{2,2,2}) \).)

4. Last, whatever the rheology, we will have recourse to the additional (but usual) assumption

\[
(\text{H2}) : ku_H|_{z=b} = O(\varepsilon). \tag{19}
\]

Indeed, we then next get \( T_{Hz}|_{z=b} = O(\varepsilon) \) from (18), so \( T_{Hz} = O(\varepsilon) \) from (17) and finally

\[
\partial_z T_{Hz} = D_t u_H + \nabla_H p - \text{div}_H T_{HH} - f_H = O(1), \tag{20}
\]

a “horizontal” projection (20) of the momentum equation that makes sense as a cornerstone for model reduction (all terms are bounded). Note that (20) is also satisfied up to additional error terms \( O(\varepsilon) \) by approximations of \( T_{Hz}, u_H, p, T_{HH} \) up to \( O(\varepsilon^{2,1,1,1}) \), assuming as usually that \( \partial_z T_{Hz}, D_t u_H, \nabla_H p, \text{div}_H T_{HH} \) are then all approximated up to \( O(\varepsilon) \).

So far, in Section 3, we have (formally) established relations that are necessarily satisfied by smooth solutions to the BVP (10)–(12)–(11a–11b) as \( h \sim \varepsilon \to 0 \) under the scaling assumptions (H1) and (H2). Moreover, using “natural” assumptions (such that all the terms \( u_H, u_z, p, T_{HH}, T_{Hz}, T_{zz} \) that appear in the equations of the initial BVP remain bounded, in particular) we have also obtained that \( u_z, p - T_{zz}, T_{Hz} \) are small terms of order \( O(\varepsilon) \) everywhere in the domain. The observations above are thus natural candidates for the construction of a reduced model whose solution coincide with an approximation

\[
(h^0, u_H^0, u_z^0, p^0 - T_{zz}^0, T_{HH}^0 - T_{zz}^0 I, T_{Hz}^0) = (h, u_H, u_z, p - T_{zz}, T_{HH} - T_{zz} I, T_{Hz}) + O(\varepsilon^{2,1,2,1,2}) \tag{21}
\]
of a solution to the initial BVP when $\varepsilon \to 0$. Such a reduced model could read e.g.

$$
\begin{cases}
D_t \mathbf{u}_H^0 + \nabla_H (p^0 - T_{zz}^0) - \text{div}_H (T_{HH}^0 - T_{zz}^0 \mathbf{I}) - \partial_z (p^0 - T_{zz}^0) - \text{div}_H T_{Hz}^0 - f_H = 0, \\
\partial_z (p^0 - T_{zz}^0) - \text{div}_H T_{Hz}^0 - f_z = 0, \\
\text{div}_H \mathbf{u}_H^0 + \partial_z u_z^0 = 0, \\
(u_H^0 \cdot \nabla_H) b - u_z^0 |_{z=b} = 0, \\
k u_H^0 + (T_{HH}^0 - T_{zz}^0 \mathbf{I}) \nabla_H b - T_{Hz}^0 |_{z=b} = 0, \\
\partial_t h^0 + (u_H^0 \cdot \nabla_H) (b + h^0) - u_z^0 |_{z=b+h^0} = 0, \\
\gamma \Delta_H (b + h^0) + T_{Hz}^0 \cdot \nabla_H (b + h^0) + (p^0 - T_{zz}^0) |_{z=b+h^0} = 0, \\
(T_{HH}^0 - T_{zz}^0 \mathbf{I}) \nabla_H (b + h^0) - T_{Hz}^0 |_{z=b+h^0} = 0,
\end{cases}
$$

where, in comparison with (10–11a–11b–11c–11d), the higher-order terms in $\varepsilon$ have been forgotten. Though, a reduced model is coherent only when a corrected approximation exists

$$
(h^0, u_H^0, u_z^0, p^0 - T_{zz}^0, T_{HH}^0 - T_{zz}^0 \mathbf{I}, T_{Hz}^0) + O(\varepsilon^{2,1,2,1,2})
$$

that is solution to the initial BVP under the same assumptions as those that have been used to define the reduced model (that is, a solution to (22) adequately corrected to solve the initial BVP should yield back (13), (14), (10), (13) and (20) with error terms of exactly the same scaling as the one observed above for the solution to the initial BVP). Coherence implies that the approximation relationship (21) may indeed hold (formally as $\varepsilon \to 0$ for smooth enough solutions) insofar as the correction terms in (23) have the right scaling in order to balance the error terms appearing in the initial BVP due to the definition of the reduced model like (22) by truncation of the initial BVP. Furthermore, similarly to the BVP (10–11a–11b–11c–11d), the system (22) is not well-posed without complementing it by equations that come from the rheology of the fluid material that it describes. Then one expects these equations to be also coherent simplifications of those equations complementing (10–11a–11b–11c–11d).

Before proceeding further to construct reduced models that are coherent for specific rheologies, let us also introduce a generic (widely used) additional manipulation of the initial equations at this stage. On noting $\mathbf{u}_H = \frac{1}{\varepsilon} \int_b^{b+h} \mathbf{u}_H + O(\varepsilon)$ whenever e.g. $\partial_z \mathbf{u}_H = O(1)$ holds (this will often be the case), one in fact often thinks of an approximation $\mathbf{u}_H^0 = \mathbf{u}_H + O(\varepsilon)$ as $\mathbf{u}_H^0 = \frac{1}{\varepsilon} \int_b^{b+h} \mathbf{u}_H + O(\varepsilon)$. Then, on noting that acceleration classically rewrites with (11a–11c) using Leibniz rule as

$$
\int_b^{b+h} D_t \mathbf{u}_H = \partial_t \int_b^{b+h} \mathbf{u}_H + \text{div}_H \int_b^{b+h} (\mathbf{u}_H \otimes \mathbf{u}_H),
$$

one often considers the “horizontal” momentum equations (20) integrated along
to physical interpretations of the reduced model.

\[ (T_{Hz} - (T_{HH} - T_{zz} I) \nabla_H (b + h))|_{z=b+h} \]
\[ - (T_{Hz} - (T_{HH} - T_{zz} I) \nabla_H b)|_{z=b} + \int_b^{b+h} f_H \]
\[ = \partial_t \int_b^{b+h} u_H + \text{div}_H \int_b^{b+h} (u_H \otimes u_H) + \int_b^{b+h} \nabla_H (p - T_{zz}) - \text{div}_H \int_b^{b+h} (T_{HH} - T_{zz} I) \]

where, recalling (13), \( p - T_{zz} \) can be approximated up to an error \( O(\varepsilon^2) \) using \( h \), i.e.

\[ \rho^0 - T_{zz}^0 = f_z (z - (b + h^0)) - \gamma \Delta_H (b + h^0). \]

Clearly, on using (18), (17), and the integrated continuity equation

\[ \partial_t h + \text{div}_H \int_b^{b+h} u_H = 0 \]

to define an approximation \( h^0 = h + O(\varepsilon^2) \), this is a priori more useful than

\[ \partial_z T_{Hz}^0 = D_t u_H^0 - f_H - f_z \nabla_H (b + h^0) - \gamma \nabla_H \Delta_H (b + h) - \text{div}_H (T_{HH}^0 - T_{zz}^0 I), \]

as a consequence coherent with (20), provided one can close

\[ \partial_t \int_b^{b+h} u_H + \text{div}_H \int_b^{b+h} (u_H \otimes u_H) = -k u_H|_{z=b} + \text{div}_H \int_b^{b+h} (T_{HH} - T_{zz} I) + h f_H + O(\varepsilon^2), \]

or the next-order evolution equation for approximate momentum \( h^0 u_H^0 = \int_b^{b+h} u_H \]

\[ + O(\varepsilon^2) \]

\[ \partial_t \int_b^{b+h} u_H + \text{div}_H \int_b^{b+h} (u_H \otimes u_H) - \text{div}_H \int_b^{b+h} (T_{HH} - T_{zz} I) \]
\[ = -k u_H|_{z=b} + h f_H + h f_z \nabla_H (b + h) + h \gamma \nabla_H \Delta_H (b + h) + O(\varepsilon^3), \]

with a coherent approximation of \( \int_b^{b+h} (T_{HH} - T_{zz} I) \) (which typically requires one to vertically integrate the rheological equations), since indeed, whenever \( \partial_z u_H = O(1) \) holds, it also holds \( \frac{1}{h} \int_b^{b+h} (u_H \otimes u_H) = \frac{1}{h} \left( \int_b^{b+h} u_H \otimes \left( \int_b^{b+h} u_H \right) \right) + O(\varepsilon) \). One may also note the latter “depth-averaged” approach invokes lower-dimensional variables that depend only on the horizontal coordinates (not \( z \)), which justifies the label “reduced model” (lower-dimensional variables are particularly useful for analytical computations as well as fast numerical simulations). And it a priori does not seem to necessarily require an explicit approximation of the shear component of the stress \( T_{Hz} \) (to close the reduced model at least). Though, to show the coherence with (18), one will in fact still need an expression for \( T_{Hz}^0 |_{z=b} \) at least; and by the way, this is also often very useful to physical interpretations of the reduced model.
**Remark 1** Assuming (H1) : $\nabla H b = O(\varepsilon)$ proved directly connected to our goal of modelling only long-waves, and shows up for instance through the dimension reduction in the reduced model [22] (where the variable $T_{zz}$ is not autonomous anymore). On the contrary, assuming (H2) : $k u_H|_{z=b} = O(\varepsilon)$ is less intuitive although it is straightforwardly connected with the useful scaling $T_{Hz} = O(\varepsilon)$ (a consequence of $k u_H|_{z=b} = O(\varepsilon)$ through $T_{Hz}|_{z=b} = k u_H|_{z=b} + O(\varepsilon)$). The latter assumption is key, in fact, to get formal simplifications like (28) or (29). Yet, this hypothesis may of course not be true in a number of flows! Then one should either use the full system of equations or another reduced model than the ones derived in the present work (then derived with another strategy).

### 4 Application to Newtonian fluids

Internal stresses in Newtonian fluids are defined, after rescaling, with a Reynolds number $Re$

$$T = \begin{pmatrix} T_{HH} & T_{Hz} \\ T_{Hz}^T & T_{zz} \end{pmatrix} = \frac{1}{Re} \begin{pmatrix} 2D_H(u_H) \\ (\partial_z u_H + \nabla_H u_z)^T \\ \partial_z u_H + \nabla_H u_z \\ 2\partial_z u_z \end{pmatrix}.$$  

Without further assumption than (H1) – (H2), one simply obtains (from $u_z = O(\varepsilon)$)

$$T = \frac{1}{Re} \begin{pmatrix} 2D_H(u_H) \\ (\partial_z u_H + O(\varepsilon))^T \\ \partial_z u_H + O(\varepsilon) \\ -2 \text{div}_H u_H \end{pmatrix}.$$  

Then, to derive a closed reduced model invoking coherent approximations of the stresses (such that $T_{Hz} = O(\varepsilon)$ in particular), one needs further assumptions. Depending on the treatment of $k u_H|_{z=b} = O(\varepsilon)$, one can in fact obtain different reduced models in the limit $\varepsilon \to 0$.

#### 4.1 The inertial regime

If we specify (H2) as

$$(31) \quad (H2a) : k \sim \varepsilon$$  

and, for the scaling of $T$ in (30) to be compatible with the relations in Section 3 further assume

$$(32) \quad (H3) : Re \sim \varepsilon^{-1}, \quad \text{and} \quad (H4) : \partial_z u_H = O(1),$$  

one first obtains $T_{HH}, T_{zz} = O(\varepsilon)$ and then the improved scalings $T_{HH} - T_{zz} I, p - T_{zz} = O(\varepsilon)$ using (H3). Moreover, because of (H4), a non-degenerate approximation $u_H^0 = u_H + O(\varepsilon)$ that does not go to zero almost everywhere when $\varepsilon \to 0$ must have a flat profile ($\partial_z u_H^0 = 0$), that is

$$(33) \quad u_H(t, x, y, z) = u_H^0(t, x, y) + O(\varepsilon),$$  

also termed a “motion by slices”. Last, (H4) suffices to justify the depth-averaging procedure introduced at the end of Section 3 for the construction
of a reduced model, so an approximation \((h^0, u_H^0) \approx (h, u_H) + O(\varepsilon^{2.1})\) may be simply determined as a solution to \((34–35)\) where the higher-order terms \(O(\varepsilon^2)\) have been neglected, i.e. the system

\begin{align}
\partial_t h^0 + \text{div} H(h^0 u_H^0) &= 0, \\
\partial_t (h^0 u_H^0) + \text{div} H(h^0 u_H^0 \otimes u_H^0) + k u_H^0 - h^0 f_H &= 0.
\end{align}

But whereas the solutions to \((34–35)\) straightforwardly allow one to construct a “first-order” approximation \((h^0, u_H^0, u_z^0, p^0) = (h, u_H, u_z, p) + O(\varepsilon^{2.1,2})\) that is coherent with the continuity equation, with \((11b)\) and with the BCs \((11a)–(14)\)

\begin{align}
(38)_{1,2} &= \\
O(\varepsilon) &\quad \text{when assumptions (H1 – H2a – H3 – H4) hold, at this stage, one still cannot compute approximations } T^0_{H_H} = T_{H_H} + O(\varepsilon^2) \text{ and it is thus not clear yet that a solution } (h^0, u_H^0) \text{ to } (34–35) \text{ also defines a coherent approximation of equations } (10) \text{ used in the derivation of } (34–35). \text{ (Note that it suffices to show that } T^0_{H_H}|_{z=b+h} = O(\varepsilon^2) \text{ and } T^0_{H_H}|_{z=b} = k u_H^0 + O(\varepsilon^2) \text{ hold.)}

\text{Fortunately, after an adequate combination of } (34) \text{ and } (35), \text{ we note that it holds}

\begin{align}
\partial_t u_H^0 + (u_H^0 \cdot \nabla) u_H^0 + k u_H^0/h^0 &= f_H
\end{align}

\text{so that the approximation proposed above would indeed be a first-order approximate solution to the horizontal projection of the momentum equation } (10) \text{ (that is } (27) \text{ without the higher order terms } O(\varepsilon) \text{ if one could construct } T^0_{H_H} \text{ such that } \partial_z T^0_{H_H} = k u_H^0/h^0 + O(\varepsilon). \text{ In fact, it is now classical that one can achieve this construction thanks to a so-called parabolic correction } [31–36]. \text{ The point is to construct an approximation } u_H = u_H^0 + u_H^1 \text{ to } u_H, \text{ with } u_H^1 \text{ a solution to } (34–35) \text{ plus possibly higher-order terms } O(\varepsilon^2), \text{ and } u_H^0 = O(\varepsilon) \text{ a correction such that one can characterize } T_{H_H} = T_{H_H} + O(\varepsilon^2). \text{ Plugging the ansatz } u_H = u_H^0 + u_H^1 \text{ for } u_H \text{ in } (27) \text{ yields, on noting } \partial_z T_{H_H} = \frac{1}{\text{Re}} (\partial^2_{zz} u_H^1 + \nabla H \text{ div } H u_H^0) + O(\varepsilon) \equiv \frac{1}{\text{Re}} \partial^2_{zz} u_H^1 + O(\varepsilon),

\begin{align}
\partial_t u_H^0 + (u_H^0 \cdot \nabla) u_H^0 &= \frac{\partial^2_{zz} u_H^1}{\text{Re}} + O(\varepsilon)
\end{align}

\text{so that, recalling } (37) \text{ for } u_H^0 \text{ solution to } (34–35) \text{ plus } O(\varepsilon^2) \text{ terms, the correction must satisfy}

\begin{align}
(38)_{1} &= \frac{1}{\text{Re}} \partial^2_{zz} u_H^1 = D_i u_H^0 - f_H + O(\varepsilon) = -\frac{k}{h^0} u_H^0 + O(\varepsilon).
\end{align}

\text{Since furthermore } \text{Re } \sim \varepsilon^{-1} \text{ and } \partial_z u_H = O(1) \text{ in } (17) \text{ imply } T_{H_H}|_{z=b+h} = O(\varepsilon^2), \text{ } (38)_{1} \text{ requires}

\begin{align}
(39)_{1} &= \frac{1}{\text{Re}} \partial_z u_H^0 = k u_H^0 b + h - z + O(\varepsilon^2).
\end{align}
Now, the trick is to require \( \frac{1}{T} \int_b^{b+h} \mathbf{u}_H^1 = O(\varepsilon^2) \), so one can build a coherent approximation \( \bar{\mathbf{u}}_H = \mathbf{u}_H^0 + \mathbf{u}_H^1 = \mathbf{u}_H + O(\varepsilon) \) of the initial BVP with a parabolic correction to \( \mathbf{u}_H^0 \)

\[
\mathbf{u}_H^1 = \frac{\text{Re}k}{2h} \left((b+3h/2-z)(z-b-h/2)+h^2/12\right) \mathbf{u}_H^0
\]

that is simply an explicit function of \( \mathbf{u}_H^0 \). On the other hand, \( \mathbf{u}_H^0 \) can indeed be computed coherently with the second-order approximation of the depth-averaged equation \( 29 \)

\[
\partial_t \left(h \mathbf{u}_H^0 + \int_b^{b+h} \mathbf{u}_H^1 \right) + \text{div}_H \left( h \mathbf{u}_H^0 \otimes \mathbf{u}_H^0 + \int_b^{b+h} \mathbf{u}_H^1 \right) + \text{div}_H \left(h \mathbf{D}_H \mathbf{u}_H^1 + \text{div}_H \mathbf{u}_H^1 \right) = h \mathbf{f}_H + h f_z \nabla_H(b+h) + h \gamma \nabla_H \Delta_H(b+h) + \frac{2}{\text{Re}} \text{div}_H \left(h \mathbf{D}_H \mathbf{u}_H^0 + \text{div}_H \mathbf{u}_H^0 \mathbf{I} \right)
\]

using \( \int_b^{b+h} \mathbf{u}_H^1 = O(\varepsilon^3) \), and \( \bar{\mathbf{u}}_H |_{z=b} = \mathbf{u}_H^0 (1 - h \text{Re}k/3). \) With the integrated continuity equation and neglecting \( O(\varepsilon^3) \) terms, one obtains a closed system of equations for \( \mathbf{u}_H^0 \)

\[
\partial_t h^0 + \text{div}_H \left(h^0 \mathbf{u}_H^0 \right) = 0
\]

\[
\partial_z \left(h^0 \mathbf{u}_H^0 \right) + \text{div}_H \left(h^0 \mathbf{u}_H^0 \otimes \mathbf{u}_H^0 \right) - \left(h^0 \mathbf{f}_H + f_z h^0 \nabla_H(b+h^0) \right) = \gamma h^0 \nabla_H \Delta_H(b+h^0) - k \mathbf{u}_H^0 (1 - h^0 \text{Re}k/3) + \frac{2}{\text{Re}} \text{div}_H \left(h^0 \mathbf{D}_H \mathbf{u}_H^0 + \text{div}_H \mathbf{u}_H^0 \mathbf{I} \right)
\]

that also defines, when \( (H1 - H2a - H3 - H4) \) hold, a coherent reduced model for a first-order approximation \( \left( \bar{h}, \bar{\mathbf{u}}_H, \bar{z}, \bar{p} \right) \) of the true solution \( \left( h, \mathbf{u}_H, u_z, p \right) \) of the initial BVP. Indeed, if we set \( \bar{h} = h^0 \), if \( \bar{\mathbf{u}}_H \) is defined as above using the parabolic correction \( 30 \) to \( \mathbf{u}_H^0 \), if we define \( \bar{\mathbf{u}}_z = u_z^0 \) and \( \bar{p} = p^0 \) like in \( 30 \), then the “horizontal” momentum equation is satisfied up to a first-order error term \( O(\varepsilon) \) (recall \( 33 \)), and the continuity equation is satisfied up to an \( O(\varepsilon) \) error term, the “vertical” momentum equation is satisfied up to an error term \( O(\varepsilon) \) (recall \( 13 \)), while \( 11a \), \( 11b \), \( 11c \) as well as \( 11d \) are satisfied up to an error \( O(\varepsilon^2) \).

Note that when \( k = 0 \), \( \mathbf{u}_H^1 \) is replaced with pure slip \( \bar{\mathbf{u}}_H \) does not depend on \( z \) anymore. Then, from \( 33 \), the stronger motion-by-slice \( \partial_z \mathbf{u}_H = O(\varepsilon) \) holds, and coherent simplifications do not need explicit approximations for \( T_{H,z} \) provided \( T_{H,z} = O(\varepsilon^2) \). In particular, an approximation \( \mathbf{u}_H \) can be straightforwardly defined from the solution \( \mathbf{u}_H^0 \).
Remark 2 (Inviscid limit and perfect fluids with shallow water equations)
Note that our scaling implies that as $\varepsilon \to 0$ the full model (Navier-Stokes equations) formally reduces to the incompressible Euler equations, while the reduced model (the so-called viscous shallow water equations) reduces to the inviscid shallow water equations without friction. But if we had considered perfect fluids from the beginning, thus $T = 0$, the choice of a motion by slice (H4) is not so much a “natural assumption” dictated by the internal stresses. This shows not only that various limit procedures do not necessarily commute, but also the importance of choosing adequate dissipation terms at the finest level of modelling (even when these terms are small). Otherwise, one encounters such infamous difficulties as the modelling of Reynolds stresses that occur in turbulence modelling.

Remark 3 (Dam break, long waves and vorticity with shallow water equations)
It may be a bit surprising that we derive the shallow water system of equations from Navier-Stokes equations under the assumption of small deformation of the free surface. Indeed, shallow water equations have been used numerically with success for a long time to simulate dam breaks, a case that does not seem to agree well with $\nabla_H h = O(\varepsilon)$. But this is consistent with the fact that inviscid shallow water equations can also be obtained as a natural limit for potential ideal flows, see e.g. [17], in regimes where surface waves with a short wavelength compared with the water depth are neglected. Now, dam breaks indeed correspond to the case of surface waves with an amplitude of order $h$ similar to the water depth that is small compared with wavelengths of order $L$ similar to a supposedly infinitely-long channel, a particular case of tidal waves [34] where viscosity and vorticity are also neglected. Besides, note that the scalings used above to obtain the shallow water equations imply in turn that the vorticity has the scaling
$$\omega = O(\varepsilon)$$
and
$$\nabla_H \wedge u_H = O(\varepsilon)$$
where $\omega = O(\varepsilon)$ must also hold since the vorticity equation
$$D_t (\omega) = \frac{1}{Re} \Delta (\omega)$$
implies
$$\omega \partial_z u_H = O(\varepsilon)$$
on using $\omega = O(1)$. So a negligible vorticity is not only a sufficient condition to obtain shallow water equations from Euler equations in some cases [17], it also seems necessary, at least in the cases where the scalings of the previous Section above hold.

4.2 The viscous regime
Instead of assuming (H2a) to achieve (H2), one can also look for a regime where $k \sim 1$ holds and

$$u_H |_{z = b} = O(\varepsilon)$$

(43)

(H2b) : $u_H |_{z = b} = O(\varepsilon)$.

Then, one should still require (H3) : $Re \sim \varepsilon^{-1}$ and (H4) : $\partial_z u_H = O(1)$ in order to next use the observations of Section 3 necessarily satisfied by smooth enough solutions. On using (H2b) and (H4), note that it holds $u_H = O(\varepsilon)$,
which is of course stronger than (H2b), thus also $u_z = O(\varepsilon^2)$ by \[11a\] and the continuity equation. This is at the basis of the \textit{viscous} regime, where viscous terms dominate in the momentum conservation. In particular, the latter rewrites (recall \[27\])

\begin{equation}
\frac{1}{\text{Re}} \partial_{zz}^2 u_H = f_H + O(\varepsilon)
\end{equation}

and after using \[17\] (in fact only $\partial_z u_H|_{z=b+h} = O(\varepsilon)$), we obtain

\begin{equation}
\frac{1}{\text{Re}} \partial_z u_H = \frac{1}{\text{Re}} \partial_z u_H|_{z=b+h} + f_H(z-(b+h)) + O(\varepsilon^2) = f_H(z-(b+h)) + O(\varepsilon^2).
\end{equation}

Note that if $\Theta = O(\varepsilon)$, this yields $\partial_{zz}^2 u_H = O(1)$, thus $\partial_z u_H = O(\varepsilon)$, and

\begin{equation}
\frac{1}{\text{Re}} \partial_{zz}^2 u_H = f_H + f_z \nabla H(b+h) + \gamma \nabla H \Delta H(b+h) + O(\varepsilon^2),
\end{equation}

so finally \[45\] with $f_H$ replaced by $f_H + f_z \nabla H(b+h) + \gamma \nabla H \Delta H(b+h)$ and an error $O(\varepsilon^3)$ (recalling that \[17\] actually implies $\partial_z u_H|_{z=b+h} = O(\varepsilon^2)$).

We next consider the boundary condition \[18\] more carefully, it reads

\begin{equation}
\frac{1}{\text{Re}} \partial_z u_H|_{z=b} = ku_H + O(\varepsilon^3)
\end{equation}

and thus yields $ku_H|_{z=b} = -f_H h + O(\varepsilon^2) = O(\varepsilon)$ in the general case, so finally

\begin{equation}
u_H = f_H \left( \text{Re} \left( (z-(b+h))^2/2 - h^2/2 \right) - h/k \right) + O(\varepsilon^2)
\end{equation}

(or $ku_H|_{z=b} = -(f_H + f_z \nabla H(b+h) + \gamma \nabla H \Delta H(b+h)) h + O(\varepsilon^3) = O(\varepsilon^2)$ if $\Theta = O(\varepsilon)$, thus the scaling $u_H = O(\varepsilon^2)$, $u_z = O(\varepsilon^3)$, and finally yielding \[45\] with $f_H$ replaced by $f_H + f_z \nabla H(b+h) + \gamma \nabla H \Delta H(b+h)$ and an error $O(\varepsilon^3)$).

Finally, we can derive an autonomous equation for $h$ using

\begin{equation}
\int_b^{b+h} f_H \left( \text{Re} \left( (z-(b+h))^2/2 - h^2/2 \right) - h/k \right) = -f_H \left( \text{Re} \frac{h^3}{3} + \frac{h^2}{k} \right)
\end{equation}

for an approximation of $\int_b^{b+h} u_H$ up to order $O(\varepsilon^3)$ (or $O(\varepsilon^4)$ depending on $\Theta$) in the integrated continuity equation $\partial_t h + \text{div}_H f_b^{b+h} u_H = 0$. The solution $h^0$ to

\begin{equation}
\partial_t h^0 - \text{div}_H \left( f_H \left( \text{Re} \frac{|h^0|^3}{3} + \frac{|h^0|^2}{k} \right) \right) = 0
\end{equation}

(with $f_H + f_z \nabla H(b+h^0) + \gamma \nabla H \Delta H(b+h^0)$ instead of $f_H$ when $\Theta = O(\varepsilon)$) allows one to define a coherent approximation of the initial BVP as long as (H1 - H2b - H3 - H4) hold, with $u_H^0$ reconstructed from $h^0$ following \[48\] (slightly modified when $\Theta = O(\varepsilon)$) and $u_z^0, p^0$ reconstructed like in the previous section. The stress terms are also easily reconstructed with $u_H^0$. 

\textit{Unified derivation of reduced models for shallow flows} \[16\]
Note that (50) is exactly (2.28) in [41], where one also comments on the fact that this reduced model is strongly reminiscent of Reynolds lubrication equation [12] except that here one has a free-surface condition, so the pressure is known to be hydrostatic, while the boundary \( z = h \) is unknown. One also compute sometimes higher-order approximations of the discharge (49) as a function of \( h \) from the momentum equation, see e.g. [14, 22, 35, 29], but the resulting models involve high-order derivatives of \( h \) (which is a difficulty for numerical simulations) and the coherence of these approximations is not obvious.

**Remark 4 (About the existence of two limit regimes)** Like the shallow water equations obtained in the inertial regime, the lubrication equation obtained in the viscous regime also has a number of applications, see e.g. [41], but this happens in different situations of course. A regime where viscous forces dominate the inertial terms to balance gravity seems to suit better with small-scale slow flows (on short times after the flow initiation and in small domains), when boundary effects are important (and \( k \) can be chosen as large as necessary to approximate the no-slip boundary condition obtained in the \( k \to \infty \) limit). On the contrary, an inertial regime seems to suit better to large-scale fast flows (on long times after the flow initiation and in large – typically geophysical – domains), when boundary effects can be reduced to a small effective friction condition on a fictitious boundary close to the real boundary inward the fluid (thereby defining a boundary layer with limited amplitude). Of course this description is only phenomenological and not quantitatively useful. Real flows are the result of particular initial and boundary conditions, and adequately choosing one of the two kinds of reduced models (or none, e.g. when boundary effects are important throughout the domain) seems difficult a priori.

Taking profit of the possible existence of two established regimes, one might also think of combining them: a viscous thin-layer where boundary effects are well taken into account could be physically meaningful as a sublayer beneath an inertial thin-layer. For instance, one may want to construct an interface \( z = b + Y \ (0 \leq Y \leq h) \) between the two layers that would define a fictitious free-surface for the former (the continuity equation would still yield an autonomous evolution equation for \( Y \) where the viscous regime holds) and a fictitious topology (possibly moving) for the latter. There is nevertheless a difficulty: such a construction would necessarily require the horizontal velocities \( u_H \) to be discontinuous at the interface (at least in the limit \( \varepsilon \to 0 \), which implies that \( \partial_z u_H \) hence also \( T_{Hz} \) is unbounded close to the interface) and the stresses at the interface to satisfy a friction law of Navier type with a coefficient \( k \) to be consistently determined with the size \( Y \) of the boundary layer. Now, there seems to exist no easy construction of such a friction law \( k \) at a fake interface yet, and we leave this difficult problem to future works (whatever the rheology). For instance, one strategy may be to find a transition layer with depth \( \eta \in (0, h - Y) \), \( \eta = o(\varepsilon) \), a velocity field \( U \) solution to the momentum equations in \( z \in (b + Y, b + Y + \eta) \), and a friction coefficient \( k \sim \varepsilon \) (possibly also a tension \( \gamma \)) such that when \( \varepsilon \to 0 \):

- the limit of \( U \mid_{z=b+Y} \) is a good approximation (at \( O(\varepsilon^2) \)) of the limit of \( u \mid_{z=(b+Y)^-} \) which is given by the velocity solution to the viscous regime in
z \in (b, b + Y),

- the limit of \( U|_{z=b+Y+\eta} \) is a good approximation (at \( O(\varepsilon) \)) of the limit of 
  \( \partial_z u, u|_{z=(b+Y+\eta)^+} \), which is given by the solution to the inertial regime in 
  \( z \in (b + Y, b + h) \) with a friction coefficient \( k \),

- \( \partial_z U/(kReU)|_{z=b+Y+\eta} \) has a limit so that Navier friction law holds at 
  \( z = b + Y \) (and one may want to define a tension coefficient \( \gamma \) at 
  \( z = (b + Y)^+ \) to formulate this).

5 Application to purely-viscous non-Newtonian fluids

Purely viscous non-Newtonian fluids can be described by a power-law model

\[
T = \frac{[D(u)]^{n-1}}{Re} \left( \frac{2D_H(u_H)}{(\partial_z u_H + \nabla H u_z)^T} \frac{\partial_z u_H + \nabla H u_z}{2\partial_z u_z} \right)
= \frac{[D(u)]^{n-1}}{Re} \left( \frac{2D_H(u_H)}{(\partial_z u_H + O(\varepsilon))^T} \frac{\partial_z u_H + O(\varepsilon)}{-2\text{div}_H u_H} \right) = \left( T_{HH} \quad T_{Hz} \quad T_{zz} \right)
\]

where internal stresses are nonlinear functions of the strain rate due to the non-constant viscosity

\[
[D(u)]^{n-1} = (|D_H(u_H)|^2 + |\partial_z u_H + \nabla H u_z|^2/2 + |\partial_z u_z|^2)^{(n-1)/2}
= (|D_H(u_H)|^2 + |\partial_z u_H + O(\varepsilon)|^2/2 + |\text{div}_H u_H|^2)^{(n-1)/2}.
\]

The degenerate constant case \( n = 1 \) has been treated in the previous section. The cases \( 0 < n < 1 \) and \( n > 1 \) are clearly different due to different monotonicity properties of the stresses with respect to the deformation gradient \( D(u) \), see e.g. [7]. The limit \( n \to 0 \) is singular: it yields a particular occurrence of the Bingham model for viscoplastic fluids with a yield stress \(|D(u)| \neq 0 \leftrightarrow |T| > \frac{2}{Re}\).

5.1 The inertial regime

Let us look for a coherent approximation of the solutions to the initial BVP when 
(\( H1 - H2a - H3 - H4 \)) hold, like in the inertial regime of the Newtonian case, so 
that the observations of Section 53 are true (at least formally for smooth enough 
solutions). In fact, only the internal stresses change in the present purely-viscous 
non-Newtonian case compared with the Newtonian case, and one can follow the 
same procedure until the construction of a correction. Then, the question is: 
can we proceed, starting from the nonlinear version of (33), viz.

\[
\frac{1}{Re}(|D_H(u_H^0)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2)^{(n-1)/2} = km b + h - z h + O(\varepsilon^2),
\]

where internal stresses are nonlinear functions of the strain rate due to the non-constant viscosity.

\[
[D(u)]^{n-1} = (|D_H(u_H)|^2 + |\partial_z u_H + \nabla H u_z|^2/2 + |\partial_z u_z|^2)^{(n-1)/2}
= (|D_H(u_H)|^2 + |\partial_z u_H + O(\varepsilon)|^2/2 + |\text{div}_H u_H|^2)^{(n-1)/2}.
\]
Unified derivation of reduced models for shallow flows

and define a correction $u_H^1 = O(\varepsilon^2)$ using the same trick as in the Newtonian case, that is $\int_b^{b+h} u_H^1 = O(\varepsilon^3)$? Notice that this is always possible when $\left|\int_b^{b+h} \partial_z u_H^1 \right| = O(\varepsilon^3)$.

For $n \geq 1$ (shear-thickening fluids), let us define the function $\phi_a : x \rightarrow (x^2/2 + a)^{(n-1)/2} x$ that is one-to-one and onto from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}_{\geq 0}$, so we can rewrite (in componentwise sense)

$$\partial_z u_H^1 = \phi_a^{-1}((\text{Re} u_H^0(b + h - z)/h) )sg(\text{Re} u_H^0(b + h - z)/h)$$

as a function of $z$ parametrized by $u_H^0$ through $a = |D_H(u_H^0)|^2 + |\text{div}_H u_H^0|^2$. Notice that it holds $0 \leq \phi_a^{-1}((\text{Re} u_H^0(b + h - z)/h) ) \leq |\text{Re} u_H^0(b + h - z)/h| $ for $z \in (b, b + h)$, and since we could do the computation $\int_b^{b+h} |\text{Re} u_H^0(b + h - z)/h| dz = O(\varepsilon^2)$ exactly in the Newtonian case, it follows that a correction $u_H^1$ such that $\int_b^{b+h} u_H^1 = O(\varepsilon^3)$ can be constructed here. One can next construct a first-order approximation $u_H^0 = u_H + O(\varepsilon)$ with the solution to (41–42) where

(i) $h^0$ is replaced by $\int_b^{b+h^0} |\text{Re} u_H^0(b + h^0 - z)/h^0| dz$ in the viscous terms of the RHS of (42)

(ii) the friction term invokes the new value of $u_H|_{z=b}$ approximated at $O(\varepsilon^2)$.

This straightforwardly defines a coherent explanation insofar as the only equation which is different from the (coherent) Newtonian case is the equilibration of second-order viscous dissipation terms with friction at the bottom boundary, and the correction term above has been constructed on purpose for that coherence to be satisfied.

Note also that this reduced model obtained for $n \geq 1$ seems new to us. Though, it is not very practical (because some terms are implicit) and may not be very useful for applications (because shear-thickening fluids are not very common in nature).

For $n < 1$ (shear-thinning fluids), we are not able to conclude about the correction with the strategy above. Instead, let us try to compare the cases $0 < n < 1$ with the limit case $n \rightarrow 0$.

For $n = 0$, assuming $|D(u)| \neq 0$ (thus $|D_H(u_H^0)| \neq 0$) the point is again to solve

$$\frac{\partial_z u_H^1}{\sqrt{|D_H(u_H^0)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2}} = \frac{\text{Re} u_H^0}{h}(b + h - z) + O(\varepsilon).$$

Now, (53) has real solutions $\partial_z u_H^1$ that are compatible with the scaling implied by (H1–H4) if, and only if, the condition $0 < |u_H^0| < \sqrt{2}/(k\text{Re})$ is satisfied.

1 This is a function of $u_H^0$ and $h^0$ that one may obtain numerically after integration $\int_b^{b+h^0} dz$ by quadrature of the terms inside $\text{div}_H$.

2 This is only known to be bounded above by $h^0 \max_{z \in [b, b + h^0]} \partial_z u_H^1 \leq \text{Re} u_H^0 h^0$. 
For $0 \leq n < 1$, one can then construct a correction that satisfies $\int_0^{b+\hbar} u_H^1 = O(\varepsilon^2)$ and define a coherent approximation of the full model provided $0 < |u_H^0| < \sqrt{2/(k\text{Re})}$ (componentwise) and $|D_H(u_H^0)| \neq 0$: in that case, the reduced model derived for $n \geq 1$ still holds. When $n \to 1$, the limit of that model still coincides (as expected) with the standard (viscous) shallow water equations, and when $n \to 0$, the correction can be computed exactly, it has the profile

$$u_H^1 = \sqrt{|D_H(u_H^0)|^2 + |\text{div}_H(u_H^0)|^2} \left( \frac{h}{\text{Re}|u_H^0|} \left( 2 \sqrt{1 - \left( \frac{\text{Re}|u_H^0|}{\sqrt{2h}} \right)^2} \right) \right) + \sqrt{1 - \left( \frac{\text{Re}|u_H^0|}{\sqrt{2}} \right)^2} + \frac{\sqrt{2}}{\text{Re}|u_H^0|} \arcsin \left( \frac{\text{Re}|u_H^0|}{\sqrt{2}} \right) \right) \frac{u_H^0}{|u_H^0|} + O(\varepsilon^2).$$

Moreover, on noting that $|D_H(u_H^0)| = 0 \Rightarrow |D_H(u_H)| = 0$ (otherwise (51) leads to a contradiction), the case $|D_H(u_H^0)| = 0$ should hold if, and only if, $|H| < \frac{2}{\text{Re}}$. So one could also obtain the reduced model starting from a variational inequality instead of (21) as full model (see e.g. [28]) and get similarly to [21] with a test function $v_H$

$$\partial_t h^0 + \text{div}_H(h^0 u_H^0) = 0,$$

$$\int_\Omega (\partial_t (h^0 u_H^0) + \text{div}_H(h^0 u_H^0 \otimes u_H^0) + k(u_H^0 + u_H^1) \cdot (v_H - u_H^0))$$

$$+ \int_\Omega \frac{2}{\text{Re}} |D_H(v_H) - D_H(u_H^0)| \geq$$

$$\int_\Omega \left( \frac{2}{\text{Re}} \text{div}_H \left( \beta \frac{D_H(u_H^0) + \text{div}_H(u_H^0)}{|D_H(u_H^0)|^2 + |\text{div}_H(u_H^0)|^2} \right) \right) \cdot (v_H - u_H^0)$$

$$+ \int_\Omega (\gamma h^0 \nabla H \Delta H(b + h^0) + h^0 f_H + f_z h^0 \nabla H(b + h^0)) \cdot (v_H - u_H^0)$$

where, using the explicit profile (55), one can compute the friction term and the viscosity modification $\beta$. But remember that the latter reduced model (in the limit $n \to 0$) breaks down when $|u_H^0| > \sqrt{2/(k\text{Re})}$ while, at the same time, it has no meaning when $|D_H(u_H^0)| = 0 \Leftrightarrow |H| < \frac{2}{\text{Re}}$, which seems contradictory.

**Remark 5 (About viscoplastic non-Newtonian fluids)** The physical pertinence and the modelling of viscoplastic non-Newtonian fluids with a yield stress is still much debated. In any case, Bingham law is a cornerstone of the viscoplastic modelling since it allows to mathematically investigate the concept of yield-stress and it is worth discussing. That is why we would also like to mention that the most usual form of Bingham law is not as above, but includes an additional viscous dissipative term, and is often thought as a particular case of the more general Herschel-Bulkley law

$$T = \left( \frac{2}{\text{Re}} |D(u)|^m + Bi \right) \frac{|D(u)|}{|D(u)|} \text{ if } D(u) \neq 0, \text{ then } |H| \geq Bi, \text{ or } D(u) = 0 \Leftrightarrow |H| < Bi,$$
where this time we have denoted $Bi$ a yield-stress independent of $\frac{\rho}{\mu}$, the usual adimensional constant for the ratio between the viscous dissipation and inertia. The standard Bingham law coincides with the case $m = 1$, while we investigated the case $m \to -\infty$ above when $n = 0$.

For any $m$, the conclusion above needs to be modified as follows, provided one assumes $Bi \sim \varepsilon$ in order to perform our thin-layer reduction procedure. As above, one cannot go further than derive a reduced-model for the subdomains of the two-dimensional domain $\Omega$ where $|D_H(u^0_H)| \neq 0$ holds. And the problem still consists in computing a correction from a profile solution to

\begin{equation}
\frac{2}{Re} |D(u)|^m + Bi \frac{\partial_z u_H^1}{\sqrt{|D_H(u^0_H)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2}} = \frac{k u^0_H}{h} (b + h - z) + O(\varepsilon^2),
\end{equation}

a polynomial equation in $|\partial_z u_H^1|$ which unfortunately does not seem to be soluble for any $m > 0$.

Another paradigm in viscoplastic modelling has attracted much attention recently, see e.g. [33], and we would like to mention it too: a Drucker-Prager yield criterion can replace Von Mises one

\begin{equation}
T = \left( \frac{2}{Re} |D(u)|^m + pBi \right) \frac{D(u)}{|D(u)|} \text{ if } D(u) \neq 0, \text{ then } |T| \geq pBi, \text{ or } D(u) = 0 \Leftrightarrow |T| < pBi.
\end{equation}

Note that it is not necessary to assume $Bi = O(\varepsilon)$ then since one already has $p = O(\varepsilon)$. In particular, when the viscous component vanishes, the correction to the velocity profile should satisfy

\begin{equation}
pBi \frac{\partial_z u_H^1}{\sqrt{|D_H(u^0_H)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2}} = \frac{k u^0_H}{h} (b + h - z) + O(\varepsilon^2),
\end{equation}

where we recall $p = f_z(z - (b + h)) - \gamma \Delta_H(b + h) + T_{zz} + O(\varepsilon^2)$. On noting [33], it holds

\begin{equation}
p \left( 1 + Bi \frac{\text{div}_H(u^0_H)}{\sqrt{|D_H(u^0_H)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2}} \right) = f_z(z - (b + h)) - \gamma \Delta_H(b + h) + O(\varepsilon^2)
\end{equation}

which, plugged into (60), yields an algebraic equation for $\partial_z u^1_H$ at any $z \in (b, b + h)$

\begin{equation}
\frac{Bi \partial_z u^1_H (f_z(z - (b + h)) - \gamma \Delta_H(b + h))}{Bi \text{div}_H(u^0_H) + \sqrt{|D_H(u^0_H)|^2 + |\partial_z u_H^1|^2/2 + |\text{div}_H u_H^0|^2}} = \frac{k u^0_H}{h} (b + h - z) + O(\varepsilon^2).
\end{equation}

In the case $\gamma = 0$ (no surface tension), the formula becomes much easier

\begin{equation}
\left( \frac{1}{2} - \left( \frac{hBi f_z}{k u^0_H} \right)^2 \right) |\partial_z u_H|^2 - 2 Bi \text{div}_H(u^0_H) \left( \frac{hBi f_z}{k u^0_H} \right) |\partial_z u_H| + |D_H(u^0_H)|^2 + (1 - Bi^2) |\text{div}_H(\partial_z u^0_H)|^2 + O(\varepsilon^2) = 0
\end{equation}
and one can then also solve explicitly the problem for the correction. So the solution to (62) allows one to define an admissible velocity correction, and thus also a coherent approximation of the full model through the reduced model, as soon as the sole requirement \(| D_H(u_H)| \neq 0 \iff | D_H(u_H)| \neq 0\) is satisfied here (a condition that unfortunately remains difficult to predict or analyze here; in particular, we are not aware of a simpler reformulation of this model as a variational inequality).

5.2 The viscous regime

Assuming \((H1 - H2b - H3 - H4)\) we again follow, for purely viscous non-Newtonian fluids, the same procedure as in the Newtonian case. First we obtain a nonlinear version of (45)

\[
\frac{1}{\text{Re}}(|\partial_z u_H|^2/2)^{(n-1)/2}\partial_z u_H = f_H (z - (b + h)) + O(\varepsilon^2)
\]

on noting \(D_H(u_H) = O(\varepsilon)\) (with additional terms to \(f_H\) if \(\Theta = O(\varepsilon)\)). With the friction boundary condition at \(z = b\), this next yields

\[
u_H = \left(\text{Re}^{\frac{n-1}{2}} a\right)^{\frac{1}{2}} \left(\frac{(z - (b + h))^{\frac{2n+1}{n+1}} - h^{\frac{2n+1}{n+1}}}{\frac{n+1}{n+1}}\right) - a\frac{h}{k} + O(\varepsilon^{1+\frac{2}{3}})
\]

where \(a = f_H\), or \(a = f_H + f_z \nabla_H (b + h) + \gamma \nabla_H \Delta_H (b + h)\) if \(\Theta = O(\varepsilon)\), and an autonomous equation for \(h^0 = h + O(\varepsilon^2)\) from the continuity equation \(\partial_t h + \text{div}_H f_b^{b+h} u_H = 0\) and the approximation

\[
\int_{b}^{b+h} u_H = \left(\text{Re}^{\frac{n-1}{2}} a\right)^{\frac{1}{2}} \left(\frac{2n+1}{n+1} h^{\frac{2n+1}{n+1}} - a h^2 + O(\varepsilon^{1+\frac{2}{3}})\right).
\]

This coincides with the viscous limit recently derived in [29], though with another mathematically-inclined viewpoint and a slightly different scaling (the term \(h^2/k\) is absent in particular, somehow a no-slip limit \(k \to \infty\)). It holds for all power-law fluids (though, note that the quality of approximation increases with \(n\) in the shear-thinning case but decreases in the shear-thickening case).

6 Application to viscoelastic non-Newtonian fluids

There are numerous models for viscoelastic non-Newtonian fluids, with various definitions of the extra-stress \(\tau\) in \(T = 2\eta_p D(u) + \tau\). We concentrate here on one prototypical model among differential constitutive equations for \(\tau\), the Upper-Convected Maxwell (UCM) equations [15],

\[
D_t \tau = (\nabla u) \tau + \tau (\nabla u)^T + \frac{1}{\lambda} (2\eta_p D(u) - \tau) \quad \text{in} \ D(t),
\]
where \( \lambda \) is interpreted as a characteristic relaxation time for elastic dilute molecules and \( \eta_p \) as a viscosity. There are many extensions to the UCM equations, which one also often writes using the total (kinematic) viscosity \( \eta = \eta_s + \eta_p \) and the retardation time \( \lambda(1 - \theta) \leq \lambda \) where \( \theta = \eta_p / \eta \in (0, 1) \)

\[
(67) \quad \begin{cases}
D_t \mathbf{u} = -\nabla p + \text{div}(2\eta(1-\theta)D(\mathbf{u})) + \text{div} \mathbf{\tau} + \mathbf{f} & \text{in } D(t), \\
\text{div} \mathbf{u} = 0 & \text{in } D(t), \\
\lambda(D_t \mathbf{\tau} - (\nabla \mathbf{u}) \mathbf{\tau} - \mathbf{\tau}(\nabla \mathbf{u})^T) = 2\eta(1-\theta)D(\mathbf{u}) - \mathbf{\tau} & \text{in } D(t).
\end{cases}
\]

A simple one for instance combines the power-law and the UCM models \( \mathbf{T} = 2\eta_s |\mathbf{D}(\mathbf{u})|^{n-1} \mathbf{D}(\mathbf{u}) + \mathbf{\tau} \), see \([39]\). One can also use nonlinear versions of the relaxation term in the right-hand side of \((66)\), see \([42]\). But \((66)\) already contains the kinematic essence of most differential constitutive equations (material frame indifference for tensors) and we postpone the discussion of other models to Remark\([6]\) (and possible future works).

To adimensionalize \((67)\), let us introduce the Deborah number \( \text{De} = \lambda / T \), and

\[
\mathbf{T} = \begin{pmatrix}
\mathbf{T}_{HH} & \mathbf{T}_{Hz} \\
\mathbf{T}_{Hz}^T & \mathbf{T}_{zz}
\end{pmatrix} = \frac{1 - \theta}{\text{Re}} \begin{pmatrix}
2\mathbf{D}_H(\mathbf{u}_H) & \partial_z \mathbf{u}_H + \nabla_H \mathbf{u}_z \\
\partial_z \mathbf{u}_H + \nabla_H \mathbf{u}_z^T & 2\partial_z \mathbf{u}_z
\end{pmatrix} + \begin{pmatrix}
\mathbf{\tau}_{HH} & \mathbf{\tau}_{Hz} \\
\mathbf{T}_{Hz}^T & \mathbf{T}_{zz}
\end{pmatrix},
\]

so the extra-stress \( \mathbf{\tau} \) satisfies the non-dimensional UCM equations

\[
(68) \quad \text{De} \left( D_t \mathbf{\tau} - (\nabla \mathbf{u}) \mathbf{\tau} - \mathbf{\tau}(\nabla \mathbf{u})^T \right) = \frac{2\theta}{\text{Re}} \mathbf{D}(\mathbf{u}) - \mathbf{\tau}.
\]

Note by the way that the cases \( \text{De} = \mathcal{O}(\varepsilon) \) are not the most physically interesting because they lead us back to a purely-viscous Newtonian extra-stress at first order of approximation in \( \varepsilon \to 0 \).

In the following, we use the reformulation of \((68)\) with the also well-known conformation tensor variable \( \mathbf{\sigma} = \mathbf{I} + \frac{\text{DeRe}}{\theta} \mathbf{\tau} \), solution to an evolution equation using the single scalar parameter \( \text{De} \)

\[
(69) \quad \text{De} \left( D_t \mathbf{\sigma} - (\nabla \mathbf{u}) \mathbf{\sigma} - \mathbf{\sigma}(\nabla \mathbf{u})^T \right) = \mathbf{I} - \mathbf{\sigma}.
\]

The infamous Weissenberg number \( \text{Wi} = \text{DeRe}/\theta \) then appears in Navier-Stokes \((10)\)

\[
(70) \quad \mathbf{T} = \frac{1 - \theta}{\text{Re}} \left( \begin{pmatrix}
2\mathbf{D}_H(\mathbf{u}_H) & \partial_z \mathbf{u}_H + \nabla_H \mathbf{u}_z \\
(\partial_z \mathbf{u}_H + \nabla_H \mathbf{u}_z)^T & -2\text{div}_H \mathbf{u}_H
\end{pmatrix} + \frac{\theta}{\text{ReDe}} \begin{pmatrix}
\mathbf{\sigma}_{HH} - \mathbf{I}_H & \mathbf{\sigma}_{Hz} \\
\mathbf{\sigma}_{Hz}^T & \sigma_{zz} - 1
\end{pmatrix},
\]

where, recalling Section\([3]\) we have also used the continuity equation, \( h \sim \varepsilon \) and (H1) in

\[
\nabla \mathbf{u} = \begin{pmatrix}
\nabla_H \mathbf{u}_H \\
(\nabla_H \mathbf{u}_z)^T \\
\partial_z \mathbf{u}_H \\
\partial_z \mathbf{u}_z
\end{pmatrix} = \begin{pmatrix}
\nabla_H \mathbf{u}_H \\
O(\varepsilon) \\
\text{div}_H \mathbf{u}_H
\end{pmatrix}.
\]

We recall that for physical reasons\([3]\), the conformation tensor should always be positive-definite, and indeed remains so as long as it is initially and solutions to \((69)\) are smooth enough (see e.g. \([20]\)).
From now on, recalling Section 3, it is natural to assume that $\sigma_{HH}$ and $\sigma_{zz}$ are not only bounded but also have the same scaling. Then, on noting that (69) reads

(71a) \[ \text{De} \left( D_t \sigma_{HH} - (\nabla_H u_H) \sigma_{HH} - \sigma_{HH} (\nabla_H u_H)^T - \sigma_{Hz} \otimes \partial_z u_H - \partial_z u_H \otimes \sigma_{Hz} \right) = \sigma_{HH} - I \]

(71b) \[ \text{De} \left( D_t \sigma_{Hz} - (\nabla_H u_H) \sigma_{Hz} - \sigma_{HH} (\nabla_H u_z) - \sigma_{Hz} \partial_z u_z - \partial_z u_H \otimes \sigma_{zz} \right) = \sigma_{Hz} \]

(71c) \[ \text{De} \left( D_t \sigma_{zz} - 2 \sigma_{Hz} \cdot \nabla_H u_z - 2 \sigma_{zz} \partial_z u_z \right) = \sigma_{zz} - 1, \]

it stems from (71a) and (71b) that (H4) \( \partial_z u_H = O(1) \) is also as natural (for boundedness) in viscoelastic non-Newtonian fluids as in purely viscous (Newtonian and non-Newtonian) fluids. Under (H4), one then obtains with $\text{De} \sim 1$

(72a) \[ \text{De} \left( D_t \sigma_{HH} - (\nabla_H u_H^0) \sigma_{HH} - \sigma_{HH} (\nabla_H u_H^0)^T - \sigma_{Hz} \otimes \partial_z u_H^1 - \partial_z u_H^1 \otimes \sigma_{Hz} \right) = \sigma_{HH} - I + O(\varepsilon) \]

(72b) \[ \text{De} \left( D_t \sigma_{Hz} - (\nabla_H u_H^0) \sigma_{Hz} + \sigma_{Hz} \text{div}_H u_H^0 - \partial_z u_H^1 \sigma_{zz} \right) = \sigma_{Hz} + O(\varepsilon) \]

(72c) \[ \text{De} \left( D_t \sigma_{zz} + 2 \sigma_{zz} \text{div}_H u_H^0 \right) = \sigma_{zz} - 1 + O(\varepsilon) \]

from (71a), (71b), (71c), for any first-order approximation $u_H^0 = u_H + O(\varepsilon)$ with a flat profile, possibly corrected by some $u_H^1 = O(\varepsilon)$.

### 6.1 The inertial regime

Like in the previous cases, we obtain an inertial limit when one specifies (H2) as (H2a) \( k \sim \varepsilon \). On the contrary, to coherently use $T_{Hz} = O(\varepsilon)$ for BCs (17) and (18) in Section 3 with (73) \[ T_{Hz} = \frac{1}{\text{Re}} \left( (1 - \theta) \partial_z u_H^1 + \theta \frac{1}{\text{De}} \sigma_{Hz} \right), \]

we should now further assume, in addition to (H4),

(i) either (H3) \( \text{Re} \sim \varepsilon^{-1} \) like in the Newtonian case,

(ii) or (H5a) \( 1 - \theta \sim \varepsilon \), plus either (H6a) \( \sigma_{Hz} = O(\varepsilon) \) or (H6c) \( \text{De} \sim \varepsilon^{-1} \),

(iii) or (H5b) \( \partial_z u_H = O(\varepsilon) \) (which is stronger than (H4)) plus either (H6a), or (H6b) \( \theta \sim \varepsilon \), or (H6c).

Note that in absence of other assumptions, $\text{De} \sim 1$ and $\theta \sim 1$ shall be simply taken as constants.
6.1.1 Small internal stresses

Under assumptions (H1 − H2a − H4 − H3), like in the Newtonian case, first-order approximations \( h^0, \mathbf{u}_H^0 \) solution to (44) are not necessarily coherent with BCs (17) and (18) and the point is how to approximately compute \( T_{Hz} \). Introducing a correction \( \mathbf{u}_H^1 \) satisfying

\[
\frac{1}{\text{Re}} \left( (1 - \theta) \partial_z \mathbf{u}_H^1 + \theta \frac{1}{\text{De}} \sigma_{Hz} \right) = k \mathbf{u}_H^0 \left( \frac{b + h - z}{h} \right) + O(\varepsilon^2),
\]

one would then like to coherently replace (44) by a reduced model invoking the depth-averaged horizontal momentum equation truncated at order \( O(\varepsilon^3) \) (so the impact of the correction \( \mathbf{u}_H^1 \) on \( \mathbf{u}_H^0 \) is coherently taken into account), just like in the Newtonian case, plus simplified UCM equations to close the system. Now, the dissipative terms involving the viscoelastic stress tensor \( T \) in the momentum equation can be computed using approximations of the UCM system of equations without any explicit reference to the correction \( \mathbf{u}_H^1 \) after rewriting (74)

\[
\partial_z \mathbf{u}_H = \frac{1}{1 - \theta} \left( \text{Re} k \mathbf{u}_H^0 \left( \frac{b + h - z}{h} \right) - \theta \frac{1}{\text{De}} \sigma_{Hz} \right) + O(\varepsilon).
\]

Then a coherent reduced model is obtained as usual after closing the second-order truncation of the horizontal momentum equation, typically using the same trick \( \int_0^{b+h} \mathbf{u}_H^1 = O(\varepsilon^3) \) as in the Newtonian case. Assuming, for the sake of simplicity,

\[
(H7a) \ : \ \partial_z \sigma_{Hz}, \partial_z \sigma_{zz} = O(1) \quad (H7b) \ : \ \partial_z \sigma_{Hz} = O(1)
\]

a profile can be computed explicitly from (75) such that \( \int_0^{b+h} \mathbf{u}_H^1 = O(\varepsilon^3) \) holds

\[
\mathbf{u}_H^1 = \frac{1}{1 - \theta} \left( \text{Re} k \mathbf{u}_H^0 \left( \frac{h^2}{3} - (b + h - z)^2 \right) - \theta \frac{1}{2 \text{De}} \sigma_{Hz}^0 (z - (h + 2b)) \right),
\]

and a reduced model coherent at first-order with (H1 − H2a − H4 − H3 − H7) reads

\[
(H7a) \ : \ \partial_t h^0 + \text{div}_H (h^0 \mathbf{u}_H^0) = 0
\]

\[
(H7b) \ : \ \partial_t (h^0 \mathbf{u}_H^0) + \text{div}_H (h^0 \mathbf{u}_H^0 \otimes \mathbf{u}_H^0) + ku_H^0 \left( 1 - \frac{\text{Re} k h^0}{(1 - \theta)^3} \right) + \frac{\text{Re} \sigma_{Hz}^0}{(1 - \theta) \text{De}} \theta (b + h^0)
\]

\[
= \left( h^0 f_H + f_h h^0 \nabla_H (b + h^0) \right) + \gamma h^0 \nabla_H \Delta_H (b + h^0)
\]

\[
+ \frac{2(1 - \theta)}{\text{Re}} \text{div}_H (h^0 (\mathbf{D}_H (\mathbf{u}_H^0) + \text{div}_H \mathbf{u}_H^0 I) + \frac{\theta}{\text{Re} \text{De}} \text{div}_H (h^0 (\sigma_{Hz}^0 - \sigma_{zz}^0 I))
\]
Further, recall that one retrieves the standard viscous shallow water (our reduced model for the standard Navier-Stokes equations) in the limit $\theta \to 0$ (prior or subsequent to $\varepsilon \to 0$; i.e., the two formal limits commute here), plus UCM equations that then become simply enslaved transport equations for a material tensor (without feedback in the momentum equation). Otherwise, this seems to be a new model. In particular, it was not identified in our previous work [18] that focused on the case $\theta = 1$ (where tangential boundary conditions like friction are a priori useless constraint for the initial BVP) because then, it is not possible to derive an expression for $\partial_z \mathbf{u}_H$ (with a link between the shear strain and the shear stress like (74) one cannot compute a coherent approximation of (72b) like (77d)). Unfortunately, the limit $\theta \to 1$ after $\varepsilon \to 0$ is unclear, but we next assume $\theta = 1 + O(\varepsilon)$ without even assuming $\text{Re} \sim \varepsilon^{-1}$ then, and will next be able to derive a limit model provided $\sigma_{Hz}/\text{De} = O(\varepsilon)$.

### 6.1.2 Small viscous internal stresses

Under assumptions (H1 – H2a – H5a – H6a), a non-vanishing first-order approximation of $\sigma_{Hz}$ can be coherently constructed from (71b) only if (H5b) holds (since $\sigma_{zz} = O(\varepsilon)$ is impossible, having as equilibrium value 1 by (16) as long as De remains bounded), which is on the other hand not coherent with (74) and the horizontal momentum equation unless $\mathbf{u}_H^0 = 0$. That is why we only consider (H1 – H2a – H5a – H6c), plus (H7) for the sake of simplicity, which leads to the reduced model

\[(78a) \quad \partial_t h^0 + \text{div}_H(h^0 \mathbf{u}_H^0) = 0\]

\[(78b) \quad \partial_t (h^0 \mathbf{u}_H^0) + \text{div}_H(h^0 \mathbf{u}_H^0 \otimes \mathbf{u}_H^0) + k \mathbf{u}_H^0 \left(1 - \frac{\text{Re} \, k h^0}{3(1 - \theta)} \right) + k \sigma_{Hz}^0 \frac{\text{Re} \, \theta(b + h^0)}{2 \text{De}}
= (h^0 \mathbf{f}_H + f_z h^0 \nabla_H (b + h^0)) + \gamma h^0 \nabla_H \Delta_H (b + h^0)
+ \frac{2(1 - \theta)}{\text{Re}} \text{div}_H(h^0 (D_H(\mathbf{u}_H^0) + \text{div}_H \mathbf{u}_H^0 I)) + \frac{\theta}{\text{Re} \, \text{De}} \text{div}_H(h^0 (\sigma_{Hz}^0 - \sigma_{zz}^0 I))\]
Under assumptions (H1 – H2a – H5a – H6c – H7ab) indeed holds.

The latter model (6.13) formally coincides with the limit $1/\text{De} \to 0, \theta \to 1$ (provided $k/(1 - \theta)$ and $1/\text{De}(1 - \theta)$ remain bounded) of (6.12), some kind of “High-Weissenberg limit” (where the UCM model suffers from deficiencies, see e.g. [20], and Remark [6] for repair suggestions).

6.1.3 Small viscous internal shear stresses

Under assumptions (H1 – H2a – H5b), the motion-by-slice is stronger than the usual one, which thus further restricts a priori the regimes of validity of a possible reduced model (even if the reduced model had solutions beyond the regime of validity of our assumptions, such solutions would not necessarily define coherent approximations of the initial BVP). It implies

\[ \mathbf{u}_H(t, x, y, z) = \mathbf{u}^0_H(t, x, y) + O(\varepsilon^2) \]

so that the correction $\mathbf{u}^1_H$ to $\mathbf{u}^0_H$ is of higher-order than usual ones and does not show up in the horizontal momentum equation if, on the other hand, the extra-stress terms can be computed coherently. Now, under (H1 – H2a – H5b – H6a – H7ab) – (H7) for the sake of simplicity – one indeed obtains the following reduced model coherent with first-order approximations of the initial BVP

\[ \partial_t \mathbf{h}^0 + \text{div}_H (\mathbf{h}^0 \mathbf{u}^0_H) = 0 \]

\[ \begin{align*}
\partial_t (\mathbf{h}^0 \mathbf{u}^0_H) + \text{div}_H (\mathbf{h}^0 \mathbf{u}^0_H \otimes \mathbf{u}^0_H) + k \mathbf{u}^0_H &= (h^0 \mathbf{f}_H + f_x h^0 \nabla_H (b + h^0)) + \gamma h^0 \nabla_H \Delta_H (b + h^0) \\
&\quad + \frac{2(1 - \theta)}{\text{Re}} \text{div}_H (h^0 (\mathbf{D}_H (\mathbf{u}^0_H) + \text{div}_H \mathbf{u}^0_H I)) + \frac{\theta}{\text{ReDe}} \text{div}_H (h^0 (\sigma^0_{HH} - \sigma^0_{zz} I))
\end{align*} \]

\[ \begin{align*}
\text{De} \left( \partial_t (\mathbf{h}^0 \sigma^0_{HH}) + \text{div}_H (\mathbf{h}^0 \mathbf{u}^0_H \otimes \sigma^0_{HH}) \right) &= h^0 \text{De} \left( (\nabla_H \mathbf{u}^0_H) \sigma^0_{HH} + \sigma^0_{HH} (\nabla_H \mathbf{u}^0_H)^T \right) + h^0 (\sigma^0_{HH} - I)
\end{align*} \]
\[(80d) \quad \text{De} \left( \partial_t (h^0 \sigma_{Hz}^0) + \text{div}_H (h^0 u_H^0 \otimes \sigma_{Hz}^0) \right) \\
= h^0 \text{De} \sigma_{HH}^0 \left( \nabla_H (u_H^0 \cdot \nabla_H b) + (\text{div}_H u_H^0) \nabla_H b - \frac{1}{2} h^0 \nabla_H \text{div}_H u_H^0 \right) \\
+ h^0 \frac{\text{De}}{1 - \theta} \left( \text{Re} \left[ \frac{1}{2} u_H^0 - \theta \frac{1}{\text{De}} \sigma_{Hz}^0 \right] \sigma_{zz}^0 + h^0 \text{De} \left( (\nabla_H u_H^0) \sigma_{Hz}^0 - h^0 \sigma_{Hz}^0 \text{div}_H u_H^0 + h^0 \sigma_{Hz}^0 \right) \\
+ h^0 \sigma_{Hz}^0 \right). \]

\[(80e) \quad \text{De} \left( \partial_t (h^0 \sigma_{zz}^0) + \text{div}_H (h^0 u_H^0 \sigma_{zz}^0) \right) = h^0 \text{De} (2 \sigma_{zz}^0 \text{div}_H u_H^0) + h^0 (\sigma_{zz}^0 - 1). \]

where, contrary to (77a–77b–77c–77d–77e) or its “High-Weissenberg limit” (78a–78b–78c–78d–78e), the shear component \( \sigma_{Hz}^0 \) of the viscoelastic stress decouples from the autonomous system of equations (80a–80b–80c–80e) and is simply computed as a post-processed solution to (80d) enslaved through \( u_H^0 \). (In (80d), we have used (74) for the vertical derivative of the horizontal velocity, and the approximate vertical velocity \( u_0^z = u_z + O(\varepsilon^2) \) reconstructed from \( u_H^0 \), the continuity equation and the impermeability condition at the bottom exactly like in the Newtonian case, so (80d) is coherent with a first-order approximation \( \sigma_{Hz}^0 = \sigma_{Hz} + O(\varepsilon^2) \).)

The latter reduced model (6.15) is exactly the viscous two-dimensional extension of the one-dimensional model derived in [18] for the case \( \theta = 1, k = 0 \). The case \( k = 0 \) (pure-slip boundary condition at bottom close to the topography) for \( \theta \in (0, 1) \) is straightforwardly recovered by taking the limit \( k \to 0 \) in the system above. One cannot compute directly the case \( \theta \to 1 \); we refer to [18] for the singular case \( \theta = 1 \) (with \( k = 0 \), where \( h^0 \) the computation of \( \sigma_{Hz}^0 \) from the horizontal momentum equation supplemented with the bottom boundary condition, and \( u_H^0 \) the computation of an approximation of \( \partial_z u_H^0 \) from an equivalent to (80d), are modified).

When one assumes (H6b–H7ab) in addition to (H1–H2a–H5b), one straightforwardly obtains the same autonomous system of equations as in the reduced model with (H6a), that is (80a–80b–80c–80e). But although it defines a coherent first-order approximation without even assuming any scaling for \( \sigma \) (a coefficient \( \theta \) of the whole tensor is then only responsible for the small scale), a first-order approximation \( \sigma_{Hz}^0 = \sigma_{Hz} + O(\varepsilon) \) of a shear component that is not smaller than the other components of the viscoelastic stress tensor would then be different, and i.e. solve

\[(81) \quad \text{De} \left( D^H \sigma_{Hz}^0 - (\nabla_H u_H^0) \sigma_{Hz}^0 + \sigma_{Hz}^0 \text{div}_H u_H^0 \right) = \sigma_{Hz}^0. \]

Last, (H1–H2a–H5b–H6c–H7ab) yields the following reduced model coherent with a first-order “High-Weissenberg-limit” approximation of the initial BVP

\[(82a) \quad \partial_t h^0 + \text{div}_H (h^0 u_H^0) = 0. \]
(82b) $\partial_t(h^0 u_H^0) + \text{div}_H (h^0 u_H^0 \otimes u_H^0) + k u_H^0$
\hspace{1cm} $= (h^0 f_H + f_H h^0 \nabla_H (b + h^0)) + \gamma h^0 \nabla_H \Delta_H (b + h^0)$
\hspace{1cm} $+ \frac{2(1 - \theta)}{\text{ReDe}} \text{div}_H (h^0 (D_H (u_H^0) + \text{div}_H u_H^0 I)) + \frac{\theta}{\text{ReDe}} \text{div}_H (h^0 (\sigma_{HH}^0 - \sigma_{zz}^0 I))$

(82c) $\partial_t(h^0 \sigma_{HH}^0) + \text{div}_H (h^0 u_H^0 \otimes \sigma_{HH}^0) = h^0 (\nabla_H u_H^0) \sigma_{HH}^0 + \sigma_{HH}^0 (\nabla_H u_H^0)^T$

(82d) $\partial_t(h^0 \sigma_{Hz}^0) + \text{div}_H (h^0 u_H^0 \otimes \sigma_{Hz}^0) = (\nabla_H u_H^0) \sigma_{Hz}^0 - \sigma_{Hz}^0 \text{div}_H u_H^0$

(82e) $\partial_t(h^0 \sigma_{zz}^0) + \text{div}_H (h^0 u_H^0 \sigma_{zz}^0) = 2h^0 \sigma_{zz}^0 \text{div}_H u_H^0$.

The various latter models obtained under assumption (H5b) cannot be easily linked to any other one. But it is remarkable that in any case, no correction to the flat profile is necessary under assumption (H5b) (even if a profile can be reconstructed afterwards from \cite{[ref]}), whereas the presence of purely (Newtonian) viscous forces is in turn hardly seen but in dissipation terms when one enforces (H5b) instead of (H5a). Furthermore, requiring the velocity to have a flat profile \cite{[ref]} is thus a priori a very strong limit for the applicability of our reduced models to real flows. This may however be particularly interesting for the cases where the normal stress differences are large, since the stress \cite{[ref]} then reads

\begin{equation}
(83) \quad T = \frac{1 - \theta}{\text{ReDe}} \begin{pmatrix}
2D_H(u_H) & O(\varepsilon) \\
O(\varepsilon) & -2 \text{div}_H u_H
\end{pmatrix} + \frac{\theta}{\text{ReDe}} \begin{pmatrix}
\sigma_{HH}^0 - I_H & \sigma_{Hz}^0 \\
\sigma_{Hz}^0 & \sigma_{zz}^0 - 1
\end{pmatrix},
\end{equation}

where either (H6b) : $\theta \sim \varepsilon$, eor (H8) : $\sigma_{HH}^0 = I + O(\varepsilon)$, $\sigma_{zz}^0 = 1 + O(\varepsilon)$, $\sigma_{Hz}^0 = O(\varepsilon^2)$ (a stronger assumption necessary when starting with (H6a) : $\sigma_{Hz}^0 \sim \varepsilon$) or (H6c) : $\text{De} \sim \varepsilon^{-1}$ holds but the viscous stretch need not be scaled even though viscoelastic components are always small.

To conclude this section, note that even though some reduced models have been identified in the High-Weissenberg limit regime (H6c) : $\text{De} \sim \varepsilon^{-1}$ where already the model is questionable, we have obtained otherwise two main reduced models – the autonomous systems of equations \cite{[ref]} and \cite{[ref]} – whose solutions define coherent approximations of the initial BVP in physically sensible regimes. It could be interesting to numerically simulate the first one, which has not been done yet to our knowledge, and maybe compare it with two-dimensional extensions of the solutions to the second model computed in \cite{[ref]}. Note in particular that shear effects are then not necessarily small in comparison with elongational/compression effects, which was a problem for the applicability of the second reduced model to real (often sheared!) flows already noted in \cite{[ref]}.

### 6.2 The viscous regime

Assuming (H1 – H2b – H4), we proceed for the viscous limit of viscoelastic fluids as usual. We specify (H2) as (H2b) : $u_H |_{z=b} = O(\varepsilon)$ and next require

\begin{align}
\text{viscous limit}
\end{align}
\(T_{Hz} = O(\varepsilon)\) as above in the inertial case, in addition to (H4) : \(\partial_t u_H = O(1)\). Recall also that the flow is necessary slow here (\(u_H = O(\varepsilon)\)) and one obtains from the momentum balance

\[
\frac{1}{\text{Re}} \left((1-\theta)\partial_t u_H + \theta \frac{1}{\text{De}} \sigma_{Hz}\right) = f_H(z - (b + h)) + O(\varepsilon^2)
\]

after using \(T_{Hz}|_{z=b+h} = O(\varepsilon^2)\) and \(f^{b+h}_z \text{div}_H(T_{HH} - T_{zz}) = O(\varepsilon^2)\).

Assuming (H3) : \(\text{Re} \sim \varepsilon^{-1}\) plus (H7) for the sake of simplicity in addition to (H1 − H2b − H4) (and of course \(\text{De} \sim 1, \theta \sim 1\) as long as nothing different is precised for these adimensional numbers) leads to a reduced model that is an autonomous system of equations for \((h^0, \sigma_{Hz}^0, \sigma_{zz}^0)\)

\[
\begin{align*}
(85a) \quad & \partial_t h^0 + \frac{1}{1-\theta} \text{div}_H \left(\frac{\text{Re}}{6} f_H |h^0|^3 - \theta \frac{1}{\text{De}} \sigma_{Hz}^0 |h^0|^2 \right) = 0 \\
(85b) \quad & \text{De} \left(\partial_t (h^0 \sigma_{Hz}^0)\right) = h^0 \sigma_{Hz}^0 + h^0 \frac{\text{De}}{1-\theta} \left(\frac{\text{Re}}{2} f_H - \theta \frac{1}{\text{De}} \sigma_{Hz}^0\right) \sigma_{zz}^0, \\
(85c) \quad & \text{De} \left(\partial_t (h^0 \sigma_{zz}^0)\right) = h^0 (\sigma_{zz}^0 - 1),
\end{align*}
\]

where the discharge in the continuity equation is computed from (84) and

\[
(86) \quad u_H = \frac{1}{1-\theta} \left(\frac{\text{Re}}{2} f_H (z - (b + h))^2 - \theta \frac{1}{\text{De}} \sigma_{Hz}^0 (z - b)\right) + O(\varepsilon^2),
\]

and the longitudinal (horizontal) stress components are obtained by the post-processing

\[
(87) \quad \text{De} \left(\partial_t (h^0 \sigma_{Hz}^0)\right) = \sigma_{Hz}^0 - I \\
+ h^0 \frac{1}{1-\theta} \text{De} \left(\sigma_{Hz}^0 \otimes \left(\frac{\text{Re}}{2} f_H - \theta \frac{1}{\text{De}} \sigma_{Hz}^0\right) \left(\frac{\text{Re}}{2} f_H - \theta \frac{1}{\text{De}} \sigma_{Hz}^0\right) \otimes \sigma_{Hz}^0\right).
\]

If furthermore \(\Theta = O(\varepsilon)\), then the same reduced model hold, but it yields coherent approximations as long as \(\partial_t u_H = O(\varepsilon)\) and \(\sigma = O(\varepsilon)\) hold, on noting the starting point

\[
(88) \quad \frac{1}{\text{Re}} \left((1-\theta)\partial_t u_H + \theta \frac{1}{\text{De}} \sigma_{Hz}\right) = (f_H - f_z \nabla_H (b+h) - \gamma \nabla_H \Delta_H (b+h)) (z - (b+h)) + O(\varepsilon^3).
\]

Assuming (H5a) : \(1 - \theta \sim \varepsilon\) and (H6a) : \(\sigma_{Hz} = O(\varepsilon)\) again requires \(\partial_t u_H = O(\varepsilon)\) and cannot be coherent, so we consider (H5a) with (H6c) : \(\text{De} \sim \varepsilon^{-1}\) only, which leads to \(\sigma_{zz} = 1 + O(\varepsilon)\) constant (equal to physical equilibrium) and a reduced model consisting of the limits of (85a) and (85b) as \(1/\text{De} \to 0\) (with obvious specificities if \(\Theta \sim \varepsilon\), and (87) for post-processing \(\sigma_{Hz}^0\) only).
Last, assuming (H5b) : \( \partial_z u_H = O(\varepsilon) \) and (H6b) : \( \theta = O(\varepsilon) \) leads to the same reduced model as the first one above (and is coherent under the more restrictive regime where \( O(\varepsilon^2) \) is replaced by \( O(\varepsilon^3) \) in (86)), while (H5b) and (H6c) gives the same as the second one above.

All these systems seem new to us: other viscous limits of non-Newtonian viscoelastic fluid models have already been derived, but on assuming different scalings, see e.g. [10, 9, 11] (De \( \sim \varepsilon \)).

**Remark 6 (Nonlinear differential constitutive equations and HWNP)**

The most used variations of the UCM model are nonlinear modifications of these differential constitutive equations, for instance the FENE-P model where the extra-stress reads \( \tau = \frac{\theta}{D_{ex}} \left( \frac{\sigma}{1 - \operatorname{tr} \sigma / b} - I \right) \), \( b > 0 \) is a new parameter such that \( 0 \leq \operatorname{tr} \sigma \leq b \) is preserved by smooth time evolutions of the flow, and the conformation tensor \( \sigma \) is solution to the nonlinear equation

\[
(89) \quad De \left( D_t \sigma - (\nabla u) \sigma - \sigma (\nabla u)^T \right) = I - \frac{\sigma}{1 - \operatorname{tr} \sigma / b}.
\]

One nice feature of these nonlinear versions is that they usually impose such constraints as \( 0 \leq \operatorname{tr} \sigma \leq b \) which are believed to alleviate the deficiencies of the UCM model (High-Weissenberg-Number Problems or HWNP in short) in the “High-Weissenberg limit” (at least, well-posedness has sometimes been shown for smooth flows, see e.g. [37]).

Furthermore, for most of them, reduced models are easily derived from the UCM reduced models above as long as one does not use (H6a) : \( \sigma_H z = O(\varepsilon) \). It suffices to multiply the last term on the right by \( \frac{1}{1 - \operatorname{tr} \sigma / b} \), which is indeed never small,

- in (77b), (77c) and (77e) under \((H1 - H2a - H4 - H3 - H7)\),
- in (82b), (82c) and (82e) under \((H1 - H2a - H4 - H5b - H6b - H7)\).

On the contrary, since \( \frac{1}{1 - \operatorname{tr} \sigma / b} \) can become arbitrary large when \( \operatorname{tr} \sigma \to b \), this is not only incompatible with (H6a) : \( \sigma_H z = O(\varepsilon) \), but also requires additional assumptions in the case (H6c) : \( De \sim \varepsilon^{-1} \) (thus not treated here).

Another way to avoid HWNP is to assume \( De \sim \varepsilon \) like in e.g. [10, 9, 11] ! Then, one cannot expect strong viscoelastic influences on the flow, of course. Though, this scaling may be enough for some applications, and we would like to mention that it has recently raised interesting new perspectives: a new approach to formal model reduction combining micro and macro scales [40] that is indeed consistent with a Newtonian behaviour in the limit \( De \to 0 \).

### 7 Conclusion

We have defined a mathematical framework that allows, for many fluids (i.e. many rheologies), to derive coherent long-wave thin-layer approximations of
free-surface Navier-Stokes flows driven by gravity above smoothly varying topographies. Most reduced models derived herein were already known, and the shallow water equations in particular have already proved useful in the numerical simulation of dam-breaks for instance. On the other hand, the models for viscoelastic fluids seem to have been much less explored, and some of those derived herein seem new to us. Of course, the question how well they model real flows is still to be answered. This could be investigated numerically in future works (letting alone their well-posedness and the mathematical control of their distance to the full model) following the same path as in our previous work [18] where we considered the viscoelastic model without friction nor surface tension in a one-dimensional (fast) inertial flow regime. Note by the way that the present work also answers important questions concerning the ability of long-wave thin-layer reduced models at describing viscoelastic fluids in sheared (as opposed to purely extensional) inertial flow regimes that were raised in [18]. Last, the non-Newtonian viscous fluids with power-law models and their viscoplastic limit have attracted much attention recently, in particular with a view to modelling avalanches and debris flows. Indeed, such complex flows seem to require complex rheologies, possibly with a yield stress and nonlinear effects, while many difficulties have been encountered so far as concerns the modelling of fluid/solid transitions. We hope that the unified framework derived herein will help characterize features essential to long-wave thin-layer flow modelling, and evaluate future models for mud flows and landslides in particular.

Acknowledgments
Thanks to Enrique Fernandez-Nieto for fruitful discussions.
