Abstract

Human nocardiosis may present as an acute or a chronic infection. Although a saprophyte Nocardia spp are responsible for superficial skin infections, pulmonary infections, and disseminated nocardiosis usually involving patients who are immunosuppressed and debilitated. Infections in immunocompetent individuals are usually chronic and present non-specific symptoms. Invasive and disseminated nocardiosis is common among patients with weakened cellular immune systems. Clinical diagnosis of pulmonary nocardiosis is difficult owing to the similarity of its presentation with other respiratory pathogens that include Actinomyces members and Mycobacterium tuberculosis. Laboratory diagnosis of human nocardiosis is plagued by the fact that a culture of Nocardia spp requires prolonged incubation periods for isolation which most laboratories fail to follow. The lack of clinical, laboratory, and epidemiological data on the incidence of nocardiosis in humans undermines its significance as a potential pathogen. This review attempts to reexamine the pathogenic potential of Nocardia in human infections.

Introduction And Background

The bacteria most commonly associated with chest infections include Haemophilus influenzae, Klebsiella pneumoniae, and Streptococcus pneumoniae, and these are the targets of antimicrobials prescribed by a physician when treating chest infections. Chest infections are also caused by other bacterial species that include members of Actinomyces spp, Bordetella pertussis, Mycoplasma pneumoniae, and Coxiella spp, which are difficult to cultivate in most laboratories [1-2]. The treatment in the case of respiratory tract infections is usually blind owing to the lack of reliable results from the sputum culture. A sputum culture should not be dismissed as valueless. If carried out correctly, it can be helpful in the management of chest diseases like acute bronchitis, chronic bronchitis, bronchiolitis, bronchiectasis, chronic pulmonary obstructive disorders (COPD), pneumonia, and cystic fibrosis, particularly when they are chronic in nature and recurrent. Using a set of a few enriched, selective and differential media, the organisms present are self-identifying and are reliably isolated. A laboratory report consisting of the identity of the bacterium and its antimicrobial sensitivity pattern can then be issued to the physician. The organisms isolated may be predictable, but with the emergence of resistance to commonly prescribed antibiotics, a specific sensitivity result is essential for guiding appropriate antimicrobial treatment [3-4].

The potential pathogens in cases of chronic chest infections are Haemophilus influenzae and Streptococcus pneumoniae followed by Klebsiella pneumoniae, Staphylococcus aureus and Pseudomonas spp. Streptococcus pneumoniae is the most common isolate in cases of pneumonia and in cystic fibrosis cases Pseudomonas spp and Staphylococcus aureus are frequent isolates. Haemophilus influenzae is commonly isolated in acute bronchitis and bronchiectasis cases usually in children, young adults and geriatric age patients. Tuberculosis is another most important lower respiratory tract infection affecting lungs and usually causes infections in immunocompromised, debilitated and nutritionally deprived individuals [5]. Other causes for chest infections include microorganisms of fungal and viral origins. Aspergillus spp (mostly A flavus and A fumigatus), Candida spp, and Cryptococcus spp cause pulmonary infections usually in immunocompromised patients, which include HIV/AIDS (human immunodeficiency virus infection/acquired immunodeficiency syndrome) patients [6-7]. Most viral respiratory tract infections predispose individuals to secondary bacterial or fungal infections necessitating antimicrobial therapy.

Review

Nocardia spp belong to the aerobic actinomycetes group (Phylum: Actinobacteria, Order: Actinomycetales) of bacteria which are gram-positive bacilli showing branching filamentous forms, are non-spore forming, and mildly acid-fast bacteria [1]. These bacteria are saprophytic and are found in soil and water [2]. Among more than 85 identified species of Nocardia, approximately 25 species are associated with human infections and include Nocardia asteroides complex (more than 50% human cases), N. brasiliensis, N. abscessus, N. cyriacigeorgica, N. farcinica, N. nova, N. transvalensis complex, N. nova complex, N. pseudobrasiliensis, and the recently reported Nocardia veteran and N. ceradoensis [8-9]. Human infection with Nocardia can result due to inhalation (pulmonary nocardiosis-pneumonia, lung abscess, and cavitary lesions) or contact with the

bacteria via a cut or abraded skin (cutaneous nocardiosis-cellulitis, ulcers), and the infection can then disseminate to the brain, kidneys, joints, heart, eyes, and bones. Nocardia spp may also result from hospital-acquired infections, usually involving catheterized patients and those who undergo surgeries (postoperative infections). Human-to-human transmission is not documented. Pulmonary infection with Nocardia spp show clinical symptoms similar to those suspected with pulmonary tuberculosis (fever, cough, chest pain, night sweats, weight loss and pneumonia). Infections with Nocardia spp usually occur in individuals with weakened immune system and can include patients suffering from diabetes, malignancies, HIV/AIDS, lung disorders like pulmonary alveolar proteinosis (plugged lung air sacs), individuals with connective tissue disorders, chronic alcoholism, transplant patients, and patients on corticosteroid therapy. In developing countries, including the United States of America, it has been noted that more than 60% of human nocardiosis occurs in immunocompromised individuals and that males are more prone to infection than females (3:1). The data on human nocardiosis is limited in the literature and is usually present as isolated case reports undermining its significance in human infection. Persistent and disseminated human infection with Nocardia cyriacigeorgica in an otherwise immunocompetent individual was reported recently in the literature which was treated employing a strategic combination therapy that lasted for more than a year. It has been noted that a delay in diagnosis among immunosuppressed patients infected with Nocardia may be responsible for treatment failure and poor prognosis. Another report which reviewed the history of human nocardiosis has revealed that clinicians should suspect infection with Nocardia and notify the same to the laboratory so that the necessary steps are taken by laboratory specialists to isolate, identify, and sensitivity pattern of the Nocardia spp. Co-infection with Nocardia spp in patients suffering from mycobacterial lung infection highlight the importance of laboratory diagnosis that may facilitate better patient management. A previous study has also elaborated on the types of radiological findings in pulmonary nocardiosis that include consolidation of the lungs, presence of nodules and masses, pleural effusion, and extension of lung infection towards the chest wall resulting in abscess. A very recent research report has elaborated on the significance of ecological and epidemiological studies on the occurrence of pathogenic Nocardia spp in the soil and environment.

**Laboratory identification of Nocardia spp**

Laboratory diagnosis of human nocardiosis includes microscopy and culture. Identification of Nocardia is more rapid, precise, and accurate with polymerase chain reaction (PCR) and 16S rDNA sequencing than with conventional phenotypic methods, which include microscopic, cultural, and biochemical properties. Modified acid-fast staining using 1% sulphuric acid as a decolorizer is employed to identify Nocardia microscopically in clinical samples, where pink colored filamentous branching bacilli are observed as shown in Figure 1.
Antimicrobial chemotherapy in nocardiosis

Although Nocardia spp are susceptible to most of the penicillin and cephalosporin group of antibiotics, the cause of concern is the probability of the emergence of antimicrobial resistance among some species [8, 35]. Antibiotics effective against gram-positive bacteria, including linezolid, ampicillin, erythromycin, and minocycline are used to treat nocardiosis. Considering the emergence of antibiotic resistance a combination of sulfonamide (trimethoprim/ sulfamethoxazole), ceftriaxone and amikacin may be preferred to treat human nocardiosis [36]. A recent paper has highlighted the significance of the organ involved, its antimicrobial susceptibility pattern, and the use of combination antibiotic therapy in the treatment of human nocardiosis [37]. A ten-year retrospective study of antibiotic susceptibility patterns of Nocardia spp isolated from the United States of America revealed that more than 50% isolates were resistant to trimethoprim/sulfamethoxazole (TMP/SMX). This study has also recommended that a combination therapy including TMP/SMX, ceftriaxone and imipenem can be initiated until the sensitivity report is available [38].

Conclusions

Clinicians, chest disease specialists, and clinical microbiologists should consider carefully the possibility of human nocardiosis. Clinical microbiology laboratories must follow standard protocols when performing sputum cultures and consider isolation and identification of Nocardia spp from various clinical specimens for better patient management in case of chest infections.
