(Received March 15, 1986)

Summary The effects of dietary sulfur-containing amino acids and glycine on plasma cholesterol level were studied in rats fed amino acid mixture diets containing cholesterol. The relationship between the amino acid composition of dietary proteins and plasma cholesterol levels was also investigated in rats fed diets containing various kinds of protein such as casein, egg albumin, pork protein, fish protein, corn gluten, wheat gluten and soy protein. Feeding the amino acid mixture corresponding to casein led to an approximately two-fold level of plasma total cholesterol as compared with feeding the amino acid mixture corresponding to wheat gluten. It was possible to reduce the plasma cholesterol of rats fed the amino acid mixture of the casein type by increasing the proportion of cystine in the total sulfur amino acids. Inversely, the deprivation of cystine resulted in an enhancement of the plasma cholesterol of rats fed the gluten type amino acid mixture. Glycine had a tendency to resist increases in the plasma cholesterol level. A significant negative correlation was noted between plasma cholesterol levels and the content of cystine in intact dietary proteins. The results suggest that the differential effect of dietary proteins on plasma cholesterol level is mainly associated with sulfur-containing amino acids included in the protein, regardless of whether it is of animal or plant origin.

Key Words plasma cholesterol, amino acid composition, methionine, cystine, glycine, dietary protein

The plasma cholesterol concentration has been shown to be affected by dietary proteins as well as other dietary components in experimental animals and humans (1-4). Although the mechanism by which dietary protein influences the plasma cholesterol level is not yet fully understood, it is probable that specific amino
acids or amino acid compositions are relevant to the influence of the protein
(2, 5–7).

Previously we offered some evidence for the possible importance of dietary
sulfur-containing amino acids and glycine in the regulation of plasma cholesterol
level in rats fed a high cholesterol diet (8, 9). Furthermore, the property of a diet
containing an amino acid mixture resembling casein or wheat gluten could be
modified by changing the amino acid contents of only three amino acids, i.e.,
methionine, cystine and glycine (10). These results suggest that the effect of dietary
protein on the plasma cholesterol level is elicited by specific amino acids, at least in
rats fed a high cholesterol diet.

The present study was designed: 1) to obtain further insight into the contri-
bution of methionine, cystine and glycine to plasma cholesterol regulation in the rat
using amino acid mixture diets, and 2) to know the relationship, if any, between the
content of each amino acid of dietary proteins and the plasma cholesterol level, using
intact proteins of various animal and plant origins.

MATERIALS AND METHODS

Male albino Wistar strain rats weighing about 80 g were used. The animals
were individually housed in suspended wire cages in a temperature-controlled
(24°C) room operated on a 12-h cycle of light (06:00 to 18:00) and dark. The
animals were fed experimental diets ad libitum for two or three weeks. The
composition of the basal (25% casein) diet was as follows (%): casein, 25; sucrose,
15; lard, 15; corn oil, 2; salt mixture, 5 (11); vitamin mixture, 1 (11); choline chloride,
0.2; cholesterol, 1; sodium cholate, 0.25; and corn starch to 100%. The basal diet
also contained 2,700 IU vitamin A, 230 IU vitamin D3 and 12 mg vitamin E per
100 g. In experimental diets, casein was replaced by other protein or amino acid
mixtures (all L-isomers, supplied by Ajinomoto Co., Ltd., Tokyo) of an approxi-
mately equivalent level of nitrogen to 25% casein. The diets containing amino acid
mixture were supplemented with zinc chloride and sodium selenite according to
Ebihara et al. (12). At the end of the feeding period, food was removed at 24:00,
and animals were sacrificed to obtain blood plasma and liver between 11:00 and
12:00 on the next day.

Experiment 1. Rats were fed diets containing 25% casein, wheat gluten or
amino acid mixture simulating casein or wheat gluten with or without modification
of the amino acid composition for 2 weeks. The diets containing wheat gluten and
its simulating amino acid mixture were fortified with 0.7% lysine·HCl.

Experiment 2. Rats were fed diets containing one of various proteins such as
casein, egg albumin, pork protein, cod protein, corn gluten, wheat gluten and soy
protein for 3 weeks. The diets containing corn gluten and wheat gluten were
fortified with lysine·HCl at levels of 0.5 and 0.7%, respectively. Pork protein and
cod protein were prepared from pork and cod minces by the extraction of lipids with
ether followed by freeze-drying. The other proteins were obtained commercially.

J. Nutr. Sci. Vitaminol.
The purities of proteins used were 95, 85, 91, 90, 75, 83 and 85% for casein, egg albumin, pork protein, cod protein, corn gluten, wheat gluten and soy protein, respectively.

The total liver lipids were extracted by the method of Folch et al. (13) and measured gravimetrically. The total cholesterol concentration of plasma and liver was measured by the method of Zak (14). High density lipoprotein (HDL) was separated by the heparin-Mn$^{2+}$ precipitation method (15) followed by the enzymatic measurement of HDL-cholesterol with a commercial kit (Wako Pure Chemical Ind., Osaka). Plasma triglycerides was measured enzymatically with a commercial kit (Wako Pure Chemical Ind., Osaka).

Experimental data were analyzed statistically by using one-way analysis of variance, and correlation coefficients were also determined (16).

**RESULTS**

*Influence of dietary sulfur amino acids and glycine on plasma cholesterol*

Table 1 shows the growth, food intake and liver weight of rats fed diets containing casein, wheat gluten or amino acid mixture simulating casein or wheat gluten with or without modification of the content of methionine, cystine and/or glycine. The body weight gains of animals fed amino acid mixture diets were generally smaller than those fed intact protein diets. When a large portion of methionine was replaced by cystine in casein-simulating amino acid mixtures, growth and food intake were depressed and liver size was enlarged, possibly due to methionine deficiency. There was no significant difference in growth and food intake among groups in gluten-simulating amino acid mixtures, irrespective of the modification of amino acid composition.

Plasma and liver lipid concentrations are summarized in Table 2. The plasma cholesterol levels of rats fed diets containing wheat gluten and its amino acid mixture were about half of rats fed diets containing casein and its amino acid mixture. When cystine content was increased at the expense of methionine in casein-simulating amino acid mixtures, the concentration of plasma total cholesterol decreased significantly. The addition of 2.5% glycine had a tendency to lower the plasma cholesterol although no statistically significant difference was observed. When the diet was deprived of cystine, on the other hand, the plasma total cholesterol level was significantly enhanced in gluten-simulating amino acid mixture diets. Glycine deprivation also had a tendency to enhance plasma cholesterol level although no statistically significant difference was observed. The proportion of HDL-cholesterol to the plasma total cholesterol was generally elevated in the groups with low plasma total cholesterol levels. In casein-simulating amino acid mixture diets, a lowering of methionine content led to a reduction of liver cholesterol and to a tendency for liver total lipids to increase.

Effects of various dietary proteins on plasma cholesterol

The growth, food intake, plasma and liver lipid concentrations of rats fed diets containing various kinds of protein are shown in Tables 3 and 4. The growth of animals fed egg albumin and corn gluten was slightly depressed as compared with the other groups. As a whole, the feeding of plant proteins resulted in lower levels of plasma total cholesterol as compared with animal proteins except for egg albumin. The proportion of HDL-cholesterol to the total cholesterol was apparently higher.

Table 3. Body weight gain, food intake and liver weight of rats fed different dietary proteins (experiment 2).

| Diet               | No. of rats | Body wt gain (g/21 days) | Food intake (g/21 days) | Liver wt (% body wt) |

in groups with lower plasma total cholesterol levels. Plasma triglyceride concentration was higher in casein-fed rats than in other groups. The contents of cholesterol and total lipid in the liver did not show obvious change either proportional or inversely proportional to the change in plasma cholesterol level.

Table 5 shows the relationship between plasma total cholesterol levels and the content of each amino acid in dietary proteins. Correlation coefficients were obtained using mean values of the plasma total cholesterol level of each group and published data on the amino acid composition for pork protein and cod protein (17) and for the other proteins used (18). A significant correlation was detected only between plasma total cholesterol levels and the cystine content of proteins. As illustrated in Fig. 1, the results indicate that the plasma total cholesterol apparently decreases as the cystine content in the diet increases.

**Discussion**

Several different explanations have been offered to account for the different effects of dietary proteins on plasma cholesterol levels, e.g., amino acid composition (2, 5–7), digestibility (19–23) and minor components attached to protein (24). However, it appears that conclusive results have not yet been obtained. Our results obtained here support the notion that specific amino acids are responsible for the effect of dietary proteins, at least under the experimental conditions used. The results of experiment 1 indicate that a diet high in methionine and low in cystine leads to a higher plasma cholesterol level, and that a diet low in methionine and high in cystine inversely leads to a lower plasma cholesterol level, although it is impossible to ascertain from this experiment whether methionine or cystine is more crucial in this effect. Dietary glycine also appears to have some effect. Thus, it is clear from present and previous (10) reports on rats fed amino acid
mixture diets that sulfur-containing amino acids and probably glycine in the diet can influence the plasma cholesterol level. These effects of specific amino acids are not, however, unexpected since it has been reported that the plasma cholesterol level was increased by the dietary addition of methionine (1, 8, 9) and was decreased by the addition of cystine (8, 9, 25, 26), glycine (9, 27) or methionine plus glycine (9) in rats fed a cholesterol-Containing diet.

In rats fed diets containing various kinds of intact proteins, on the other hand, the plasma cholesterol level had a significant negative correlation with the cystine content of dietary proteins, but not with other amino acids (experiment 2). This partially supports previous results by Sautier et al. (28); they showed that serum cholesterol levels in rats fed cholesterol-free diets containing casein, whey protein, soy protein and sunflower protein had a significant positive correlation with tyrosine and glutamic acid, and a negative correlation with cystine and alanine, and suggested that the effect of dietary proteins on serum total and HDL-cholesterol level could be related to the ratio of (tyrosine + glutamic acid): (cystine + alanine). Although it has been noticed that animal proteins, as compared with plant proteins, have a tendency to contain higher levels of methionine (29), it might also be necessary to take into consideration the fact that plant proteins generally contain relatively higher levels of cystine as shown in Fig. 1. It is of interest in this connection that some types of animal protein such as egg albumin and whey protein (28) contain higher levels of cystine and that these proteins have a serum or plasma cholesterol-lowering effect despite their animal origin. Sautier et al. (28) have already noted that the hypocholesterolemic effect of dietary protein is not always related to plant origin, on the basis of the fact that whey protein has a cholesterol-lowering effect. Furthermore, Jenkins et al. (30, 31) also have presented evidence showing that animal proteins do not necessarily lead to a higher plasma cholesterol level compared with plant proteins. Thus, it is evident that the effect of dietary proteins cannot be fully explained on the basis of the classification of proteins by animal or plant origin. The results obtained in the present study prompted us to propose that dietary proteins might be roughly classified with respect to plasma cholesterol regulation in rats as cystine-rich and cystine-deficient proteins, regardless of their origin. This does not, however, exclude the importance of methionine and probably glycine contents as shown in experiment 1 with amino acid mixture diets. Further studies are needed to test the above hypothesis.
