Abstract: Medial opening-wedge high tibial osteotomy (OW-HTO) is an excellent surgical option for patients with varus knee osteoarthritis. Medial collateral ligament (MCL) release and posterior neurovascular structure protection during OW-HTO are steps that often induce stress and nervousness during surgery, especially for surgeons in the earlier stages of their learning curve. While it is well-known that the MCL should be released during OW-HTO, the standard retraction techniques pose challenges in visualization and instrument placement in the surgical field. We present our technique, which illustrates an alternative method to manage the MCL and safely protect the neurovascular structures using a second and more posterior surgical window during OW-HTO.

The medial opening-wedge high tibial osteotomy (OW-HTO) is a robust surgical option for treatment of medial compartment osteoarthritis with varus malalignment.1 Despite good outcomes, complication rates following OW-HTO have been consistently reported to be around 30%.2 Although rare (1.7%), neurovascular injury following OW-HTO is devastating when it occurs.2 To prevent neurovascular injury, several techniques have been previously described, including the use of a protective cutting system,3 patient-specific cutting guides,4 and computer-assisted navigation.5 There has been much discussion about the management of the medial collateral ligament (MCL) following OW-HTO.6,7 It is well-known that the MCL has to be released in OW-HTO.6 In a standard approach for OW-HTO, the MCL is raised subperiosteally to the posteromedial tibia before a large retractor is placed behind the tibia to protect the neurovascular structures (NVS). However, the surgical assistant often has to fight against the resistance of the intact MCL, and this poses challenges in visualization and instrument placement in the surgical field. The purpose of this article is to present, in detail, a technique to manage the MCL and safely protect the NVS using a second and more posterior surgical window during OW-HTO.

Surgical Technique (With Video Illustration)

Positioning and Draping

After induction of general or spinal anesthesia, the patient is positioned supine. The use of a pneumatic tourniquet is based on surgeon’s preference. The leg is prepared and draped in a sterile fashion.

Diagnostic Arthroscopy

A diagnostic arthroscopy is performed to confirm medial compartment disease and exclude significant chondral lesions in the lateral and patellofemoral compartments.

Surgical Procedure

The surgical procedure is presented in Video 1. To summarize, the knee is positioned in a flexed position. A medial approach to the proximal tibia is performed with an oblique skin incision running from the posterosuperior to anteroinferior aspect, starting 2 cm below the tibiofemoral joint line and extending 5 to 6 cm toward the distal tibia (Fig 1). The edge of the patellar tendon is then bluntly dissected and marked in preparation for the biplane osteotomy cut along the tibial tubercle. A subcutaneous soft-tissue dissection exposes the pes anserinus. The pes anserinus is dissected by inserting and spreading the jaws of an Overholt clamp (Fig 2). After its posterior retraction, the vertical fibers of the MCL are easily identified. Instead of retracting the MCL and placing a posterior retractor from its anterior border, we create a second soft-tissue window at the posterior border of the MCL (Fig 3). Starting at the posterior border of the MCL, a periosteal elevator is used to dissect the soft tissue until the posterior cortex of the tibia is reached and the popliteus muscle carefully released (Fig 4). This elevator is then left in place to guide the posterior tissue retractor (Newclip Technics, Nantes, France) between the posterior cortex and popliteus muscle (Fig 5).

Fig 1. Anatomical landmarks to determine skin incision.

Fig 2. An Overholt clamp is placed underneath the hamstrings and the jaws are opened to release them.

Fig 3. Demonstration of a window being created posterior to the superficial MCL to allow access to the posterior cortex. (MCL, medial collateral ligament.)

Fig 4. A periosteal elevator is run along the posterior tibial cortex to create a safe passage for the neurovascular protector. (MCL, medial collateral ligament.)
This step can be done with the knee in flexion to facilitate insertion. After the posterior tissue retractor (PTR) has been inserted, the periosteal elevator is removed progressively and is used as a “feeler” to palpate the posterior aspect of the tibia and with 180° twists, used to confirm that there is no intervening soft tissue trapped between the posterior aspect of the tibia and the PTR. The deep MCL and proximal tibial attachment of the MCL remain attached. The distal part of the superficial MCL is then released and a small Hohmann retractor is used to retract it, presenting the medial proximal tibial surface for the osteotomy (Fig 3). Following the saw cuts for the osteotomy under fluoroscopic control, a metal ruler or a chisel is used to palpate the PTR through the osteotomy gap to confirm that the posterior tibial cortex has been completely osteotomized. The wedge opening is then performed by placing a spreader device, posterior to the MCL along the cut posterior cortex. The MCL tension can be assessed and a pie-crusting technique can be used for further fine-tuning. Usually, a small release of the posterior fibers of the MCL allows sufficient lengthening, while maintaining the integrity of the superficial MCL (Fig 6). The rest of the procedure can be undertaken in standard fashion.

**Postoperative Protocol**

Patients are allowed to weight bear fully if tolerated, with full range of motion and if needed, with the aid of crutches. Chemoprophylaxis against venous thromboembolism is prescribed for 3 weeks.

**Discussion**

The OW-HTO is an excellent option for younger patients with varus osteoarthritis, given that outcomes following total knee arthroplasty in this patient group are poor. While OW-HTO has been gaining popularity in recent years, it has been shown that the learning curve for OW-HTO ranges from 27 to 42 procedures. Despite good outcomes, complication rates following OW-HTO have been consistently reported to be around 30%. We believe that our described technique can reduce the complications of tibial plateau fractures as well as neurovascular injuries.

Tibial plateau fractures following OW-HTO has an incidence that ranges from about 1% to 11%. This usually occurs from an incomplete osteotomy. With our technique, we can confirm that there is no intervening soft tissue between the PTR and the posterior cortex of the tibia. The surgeon can then confidently complete the planned osteotomy cut, leaving the lateral hinge intact. This should reduce the risk of tibial plateau fractures.
According to the literature, there are anatomical variants in the division of the popliteal artery. An aberrant high branching of the anterior tibial artery running posterior to the popliteus muscle has been previously reported.\textsuperscript{12,13} Therefore, placement of the PTR after releasing of the popliteus off the posterior aspect of the proximal tibia will offer excellent protection of the NVS while the surgeon saws the posterior tibial cortex. Feedback of contact between the saw tip and the PTR confirms that the posterior cortex has been osteotomized. Although rare (1.7%), neurovascular injury following OW-HTO is devastating when it occurs.\textsuperscript{2}

Besides offering complete protection of the NVS, positioning the posterior retractor through a second surgical window along the posterior border of the MCL allows us to perform a controlled and patient-specific release following opening of the osteotomy. We could potentially prevent both excessive pressure (from under-release) on the medial compartment and medial instability (from over-release). Our technique also has some disadvantages. A broad and sharp periosteal elevator is required to dissect the soft tissue until the posterior cortex of the tibia is reached and the popliteus muscle carefully released. Without the appropriate tool, there is danger of injuring the neurovascular structures. The advantages and disadvantages of our technique are presented in Table 1.

To conclude, we are convinced that by creating a secondary window posterior to the MCL allows excellent protection of the posterior neurovascular structures, prevents collision of retractors and the power instruments, and allows us to perform a more controlled release of the MCL following the osteotomy.

### Table 1. Advantages and Disadvantages of the Second Window Approach

| Advantages | Disadvantages |
|------------|---------------|
| Prevention of excessive tension on MCL | Potential injury to posterior neurovascular structures without appropriate instruments |
| Excellent protection of posterior neurovascular structures | |
| Offers opportunity for more controlled release of MCL following osteotomy | |

MCL, medial collateral ligament.
