Abstract

In this paper we introduce a new method for analysing Milky Way phase-space which allows us to reveal the imprint left by the Milky Way bar and spiral arms on the stars with full phase-space data in Gaia Data Release 2. The unprecedented quality and extended spatial coverage of these data allowed us to discover six prominent stellar density structures in the disc to a distance of 5 kpc from the Sun. Four of these structures correspond to the spiral arms detected previously in the gas and young stars (Scutum-Centaurus, Sagittarius, Local, and Perseus). The remaining two are associated with the main resonances of the Milky Way bar where corotation is placed at around 6.2 kpc and the outer Lindblad resonance beyond the solar radius, at around 9 kpc. For the first time we provide evidence of the imprint left by spiral arms and resonances in the stellar densities not relying on a specific tracer, through enhancing the signatures left by these asymmetries. Our method offers new avenues for studying how the stellar populations in our Galaxy are shaped.

Key words. Galaxy: evolution – Galaxy: kinematics and dynamics – Galaxy: structure – Galaxy: disk

1. Introduction

A long-standing problem in galactic dynamics is how gravitational instabilities of stellar discs shape the large-scale morphology of galaxies, and in particular their conspicuous spiral arms. While the spectacular images of spiral galaxies mainly reflect young stars formed from interstellar gas in spiral arms, all disc stars can cross the arms and contribute to their overdensities; therefore, the entire disc should bear the imprint of its spiral structure. In the Milky Way, the position of our Solar System near the plane of our Galaxy, distance uncertainties, and interstellar extinction have complicated attempts to learn directly about these asymmetries. Our method offers new avenues for studying how the stellar populations in our Galaxy are shaped.

2. Data and methods

We used Gaia DR2 sources for which the 6D phase-space coordinates can be computed, that is all sources with an available five-parameter astrometric solution (sky positions, parallaxes, and proper motions) and radial velocities (Gaia Collaboration et al. 2018b). A large number of kinematic arches with various morphologies not known prior to Gaia were found (Ramos et al. 2018; Kushniruk & Bensby 2019; Monari et al. 2019) and large-scale wiggles were discovered in the $V_\phi$ – $R$ plane (Kawata et al. 2018; Antoja et al. 2018). These features can be interpreted as the signature of the impact of an external perturbation (D’Onghia et al. 2016; Laporte et al. 2019) or as evidence of the spiral structure and the bar of the Milky Way (Hunt et al. 2018; Fragkoudi et al. 2019). At the same time, in the solar vicinity the Galactic spiral structure is believed to generate various patterns in the phase-space (Siebert et al. 2012; Williams et al. 2013), but uncertainties on the location and strength of the spiral arms have so far prevented us from explaining the observed patterns. In this work, we use the high-quality Gaia DR2 sample of stars with radial velocities (hereafter GRV2), together with a new method to highlight the stellar density structures, to explore the Milky Way spiral arms without relying on any specific stellar tracer. The outline of the Letter is as follows: in Sect. 2 we describe the data and the method we used; in Sect. 3 we examine the phase-space structure of the Milky Way and compare its various features with Milky Way-type galaxy simulations; and in Sect. 4 we summarize the conclusions that can be drawn from our study.

* Here be dragons, a phrase famous in medieval cartography when dragons and sea monsters were used to designate uncharted and possibly dangerous regions.
2018a). From this sample we selected stars with positive paral-
laxes, and relative errors on parallaxes of less than 10%. Dis-
tances were computed by inverting parallaxes. For calculat-
laxes, and relative errors on parallaxes of less than 10%. Dis-
2018a). From this sample we selected stars with positive paral-

The detection of stellar structures in the Galaxy faces two
problems of different natures. On the one hand, the epicyclic
motion of stars, which is the radial oscillation around their guid-
ing centres, blurs all kinds of morphological features in discs.
This effect is clearly seen in galactic structures made of multi-
ple stellar populations with different kinematics, making any den-
sity structure more evident for younger, dynamically colder stel-
lar populations with lower orbital eccentricities (Debattista et al.
2017; Khoperskov et al. 2018). On the other hand, the Gaia
and Gaia RVS limiting magnitudes, the shape of the Gaia
footprint, and the effect of extinction have the consequence of limiting the
accessible portion of the disc to a few kpc from the Sun, with a
density of sources that decreases rapidly with distance from the Sun.
We also investigated the sensitivity of our results on the Gaia parallax biases (Schönrich et al. 2019) and did not
find any systematic changes in the structures we discovered.

To test the possible effects of extinction, we investigated a cross-matched sample between GRV2 and WISE (Wilson &
Naylor 2018). We selected stars in this sample with absolute W1 magnitude in [−1,−2], and considered the redder and bluer
half in G-W1 colour separately. We found that the redder half of this sample, expected to contain a larger fraction of reddened
stars, showed a significantly noisier representation of structures in guiding space than the bluer half, as well as a dominant extinc-
tion feature in the direction of the Galactic centre. This sug-
gests that the guiding space structures seen in GRV2 are not the
result of sample biases due to extinction, but that, on the con-
trary, extinction likely reduces the amplitudes of the structures
we found. Therefore, our estimates of their amplitudes should be
considered as lower limits.

In order to understand what causes these structures we con-
side two Milky Way-type galaxy simulations. The first is an N-
body/SPH simulation of a spiral galaxy (Model I, see details of the model in Appendix A) in which the spiral structure in the stel-
lar disc is weak and blurred by the epicyclic motions of the stars
(see Fig. 2a). However, transforming the positions of the simu-
lated stars to guiding coordinate space using Eq. (1) allows us to
recover narrow spiral arm-like features (see Fig. 2b) whose mor-
phology is in much closer agreement with the gas surface density
map than the original stellar density (see Appendix A). For the

3. Results

Figure 1 (top) shows the mean density map $\rho(X_g,Y_g)$ for 100 re-sampled selections of stars where several horizontally
extended overdensity features can be found across the entire disc area covered by Gaia DR2. To sharpen even more the features
seen in the $\rho(X_g,Y_g)$ map, we produce a residual map by using an unsharp masking approach. In Fig. 1 (bottom), we show the
residual map defined as

$$\delta \rho(X_g,Y_g) = \rho(X_g,Y_g) - \langle \rho(X_g,Y_g) \rangle,$$

where $\langle \rho(X_g,Y_g) \rangle$ denotes the mean number density map con-
structed by convolving the density distribution $\rho(X_g,Y_g)$ with a
2D Gaussian kernel of width 400 pc. The combined re-sampling technique and transformation to guiding coordinates reveal sev-
eral new stellar density structures.

Figure 1b shows the stellar density now plotted in the guid-
coordinating space $(X_g,Y_g)$. Large-scale overdensities of length
3–8 kpc in guiding coordinates cover most of the disc observed by Gaia. Structures are seen even more clearly once the unsharp
masking is applied. The result is presented in Fig. 1d, where six
outstanding narrow overdensities of $\approx 5\%$ amplitude are vis-
ible. The most prominent features are seen close to the solar
radius: one crosses the line from the Sun to the Galactic centre
at $Y_g \approx -7$ kpc, and another passes through the solar vicinity
at $Y_g \approx -8$ kpc. Two additional structures are detected in the inner
galaxy, between $Y_g = -4.5$ and $Y_g = -6$ kpc. In the outer disc,
we find an extended structure between $Y_g = -9$ and $Y_g = -10.5$ kpc
and a smaller one just beyond the solar radius between $Y_g = -8$
and $Y_g = -9$ kpc. Coloured lines in Figs. 1c,e highlight the main
structures that appear in the guiding coordinate space.

In order to reduce the effect of the Gaia DR2 selection func-
tion, we apply an approach based on a re-sampling of the face-
on density map in the spatial coordinates. First, we introduce a
uniform Cartesian grid in spatial coordinates $(X,Y)$ with the
cell size of $100 \times 100$ pc$^2$. Then we populate each grid cell by
100 randomly selected stars located within this cell. Such a sin-
gle sampling procedure results in a constant number of stars in the
$(X,Y)$-plane on the Cartesian grid. Then by repeating ran-
dom re-sampling for each cell of the $(X,Y)$-grid we generate 100
independent selections of stars from the entire Gaia DR2, where
each subsample contains $100 \times 100 \times 100 = 10^6$ stars. Thanks
to the large statistics of the Gaia DR2 catalogue, we can re-
populate our $(X,Y)$-grid by different subsamples of stars, with
repetitions, especially far beyond the solar vicinity where the
number of the observed stars is lower. Then each subsample of
stars (with a flat distribution in $(X,Y)$-coordinates) is converted
into $(X_g,Y_g)$ guiding phase-space map (see Eq. (1)) where the
flat distribution in $(X,Y)$ plane transforms into a map depicting
several large-scale features.
simulated stars in each of these features we calculate the distribution of radial velocities (see Fig. 2c; more details in Appendix A). In each histogram we see a systematic inward motion, with the radial velocity distribution skewed towards negative values. This pattern is in agreement with predictions of density wave theory where, within corotation, the stars in the spiral arms move towards the galactic centre (Lin et al. 1969; Siebert et al. 2012; Faure et al. 2014; Pasetto et al. 2016; Monari et al. 2016).

Another non-axisymmetric structure that could generate features in the guiding coordinate space is a stellar bar which gives rise to a number of resonances in the outer disc. In Figs. 2d–f we show the results from a snapshot of an N-body simulation of a barred galaxy without prominent spiral structure (Model II; see details in Appendix A). Here, two narrow quasi-circular overdensities appear in the guiding coordinate space outside the bar which are absent in the spatial density map. Spectral analysis of the orbits of particles in these overdensities confirms that these features are at the bar’s corotation and outer Lindblad (OLR) resonances (see Appendix A for details). The observed kinematics of stars at the bar resonances depend on both the bar orientation and the distribution of stellar orbits. In particular, some stars near corotation follow orbits elongated along the bar major axis, showing periodic variations of their radial velocities. The bar OLR is populated by two orbital families with proportions varying along the OLR region. When the bar is oriented as it is in the Milky Way, and an area of the simulated disc is considered similar to that available with GRV2 (Y < 0, |X| < 5 kpc), we find that the OLR region is dominated by r1(2) orbits (Fragkoudi et al. 2019) that move outwards. This makes the mean radial velocity as seen from the Sun positive, with a velocity distribution skewed towards positive values. At the same time stars near corotation show different kinematics with more symmetric radial velocity distribution (see Fig. 2f and Appendix A for details).

We conclude from these theoretical models that both the spiral arms and major bar resonances are imprinted in velocity space. The extended spatial coverage, high sampling (even far from the solar vicinity), and unprecedented precision of the Gaia DR2 data allow us to see these signatures in the observed velocities. Figure 2g shows that four of the overdensity structures obtained in Fig. 1 with the guiding space analysis (SDS 1, SDS 3, SDS 4, and SDS 6) have systematically negative radial velocity with a radial velocity distribution skewed towards negative values, just as the spiral arms in the simulated galaxy of Model I. Meanwhile SDS 2 has a wide and more symmetric distribution with only a small mean negative velocity, and stars in SDS 5 tend to move outwards as seen from the Sun, with the velocity distribution skewed towards positive values (see Fig. 2h), very similar to the barred galaxy simulation Model II.

We can also transfer the structures in Fig. 1 back to original Galactic plane coordinates (see Appendix B). To place all structures in the Galactic plane, we estimate their mean location by using Gaussian fitting along the galactocentric radial direction with 1D Gaussian models. Figure 3a shows the inferred locations of the Milky Way spiral arms (SDS 1, 3, 4, 6). Overplotted are the positions of known high-mass star-forming regions (HMSFRs) with accurate VLBI maser distances (Reid et al. 2014; Xu et al. 2016) which trace the Milky Way spiral arms in gas and young stars. These sample the Perseus arm (purple), the Local arm (orange), the Sagittarius arm (blue), and the Scutum-Centaurus arm (turquoise). The location of these HMSFRs is in excellent agreement with the stellar overdensities we find. The Local arm and the Perseus arm perfectly overlap with SDS 4 and SDS 6, the fourth and the sixth (from the Galactic centre) stellar density structures discovered in this study. The star-forming regions in the inner disc (associated with the Sagittarius arm and the Scutum-Centaurus arm) are spatially coincident with SDS 1 and SDS 3, the first and third of the discovered stellar structures; a few HMSFRs connecting SDS 1 and SDS 3 also overlap with SDS 2.

Fitting a logarithmic spiral arm model to the data in Fig. 3a, we measure the pitch angles (Davis et al. 2012) for the spiral arm structures (SDS 1, 3, 4, 6), from the inner to outer arm 14.7 ± 1.1◦, 10.8 ± 0.8◦, 5.8 ± 0.7◦, and 7.7 ± 0.7◦, respectively. Therefore, our results suggest that the Milky Way has a four-armed spiral, in agreement with a number of studies of Milky Way spiral structure based on different tracers and techniques (Vallée 2014; Reid et al. 2019), although some previous results are in favour of m = 2 pattern (e.g. Siebert et al. 2012).
Fig. 2. Milky Way-type galaxy simulations and kinematic properties of the overdensities in the Milky Way disc. *Panels a–c:* Milky Way-type spiral galaxy (Model I). The stellar surface density in (a) shows only marginal evidence of density waves because they are blurred by epicyclic motions. After the transformation to guiding coordinate space (b), the model spiral arms are much clearer and show a morphology similar to the gas density (see Appendix A). These maps are shown in log-scale. *Panel c:* stellar radial velocity distributions for the four spiral arms highlighted in panel b where the mean radial velocity within the arms is negative (inwards), exactly as expected from density wave theory (Lin et al. 1969). *Panels d–f:* Milky Way-type barred galaxy (Model II). Transforming stellar surface density (e) to guiding coordinate space (f) shows prominent overdensities at the bar’s corotation (CR) and outer Lindblad (OLR) resonances, as determined from spectral analysis in Appendix A. *Panel g:* shows a broad, nearly symmetric radial velocity distribution for stars at CR (blue), as viewed from the solar position at \((x, y) = (0, -8.2)\) kpc, and an outward-skewed distribution at OLR (red). *Panels g and h:* kinematics of stars in *Gaia* GRV2 associated with the large-scale stellar overdensities (SDS) detected in guiding coordinate space (see Fig. 1). *Panel g:* radial velocity distribution for four structures (SDS 1, 3, 4, 6) reveals a mean radial motion towards the galactic centre similar to that seen in the spiral arms of Model I. *Panel h:* radial velocity distributions in SDS 2, 5 resemble the distributions at CR and OLR in the in the barred galaxy Model II. Error bars on all profiles are determined as described in Appendix A.

![Fig. 2](image)

Fig. 3. Milky Way spiral arms and bar resonances revealed by *Gaia* DR2. *Panel a:* *Gaia* DR2 based spiral arms shown by symbols with error bars, while two grey-shaded areas show the location of stars likely associated with corotation and OLR of the Milky Way bar, all structures were identified using guiding coordinate space densities and radial velocity distributions. Large symbols without error bars depict the position of high-mass star-forming regions with trigonometric parallaxes measured by the VLBA (Reid et al. 2014). These sources trace the gaseous and young star spiral arms in the Milky Way (Scutum-Centaurus, Sagittarius, Local, and Perseus). The grey oval represents the orientation of the Milky Way bar, and the solar position is indicated by a yellow star. *Panels b and c:* two new artistic renderings of a Milky Way spiral galaxy including the four-armed tightly wound spiral arms revealed by *Gaia* DR2. Modified images of original Milky Way galaxy rendering by Robert Hurt and Nick Risinger.

Interestingly, the Local arm, which is the closest spiral arm to the Sun, appears to be a tightly wound structure, located between the two primary arms of the Milky Way, Sagittarius and Perseus. This result supports the idea that the Local arm is an intrinsic spiral arm, rather than an inter-arm spur as has been suggested for a long time (Elmegreen 1980; Scoville et al. 2001; La Vigne et al. 2006; Miyachi et al. 2019).

The SDS structures associated with the Milky Way bar resonances (SDS 2 and SDS 5) are shown as grey-shaded regions in Fig. 3a where corotation is placed at \(R \approx 6.2\) kpc and the OLR is just beyond the solar radius, at \(R \approx 9.3\) kpc. We note that the derived location of the resonances could correspond to a fraction of the entire resonance structure which is supported by our Model II, where both CR and OLR regions cover wide radially extended areas across the disc (see Figs. A.2 and B.1). This issue of completeness of the detected OLR stars in the disc beyond the Sun will be resolved by applying the approach presented here to stars with radial velocities in the forthcoming *Gaia* DR3. Although the Milky Way bar itself is not covered by our GRV2 sample, the location of the bar resonances allows us to estimate its angular rotation speed. For the significantly declining rotation curve of the Milky Way (Eilers et al. 2019) we obtain...
values of $37-42\, \text{km s}^{-1}\text{kpc}^{-1}$ in good agreement with recent in situ estimates from Milky Way bar kinematics and dynamics (Portail et al. 2017; Sanders et al. 2019; Bovy et al. 2019).

4. Conclusions

Understanding the global structure of our Milky Way, in all its constituents, is a classical problem of Galactic astronomy. Mapping the main non-axisymmetric features in the disc, as traced by their stars, is an important advance made possible only by the superb quality of the Gaia DR2 data; to date the Galactic spiral arms had only been detectable with young stellar populations and gas. In this paper we provide a means for identifying stars of spiral arms and bar resonances without relying on a specific stellar tracer, opening up several further avenues towards understanding the Milky Way.

For the first time we revealed the imprint left by the Milky Way bar and spiral density waves on the entire disc population; the Gaia Data Release 2 enabled us to recover the prominent four-arm spiral structure of the Galaxy (Scutum-Centaurus, Sagittarius, Local and Perseus spiral arms) to a distance of 5 kpc from the Sun (see Figs. 3b,c). We also independently constrained the Milky Way bar parameters by detecting the prominent signatures of its main resonances, which together with the properties of spiral arms provide us a much more complete picture of the asymmetries present in the disc of our Galaxy, and never seen before by Gaia. The presence of the bar and extended spiral structure evidently induce in-plane phase-space perturbations that imply that the Milky Way stellar disc is out of equilibrium on large scales, and most of the features in the velocity space are related to the presence of these non-axisymmetric structures in the disc.

In this work we also described a new idea for analysing the Milky Way stellar populations, which in combination with Gaia data and spectroscopic information (WEAVE, MOONS, 4MOST) will allow us to study stellar dynamics in the vicinity of the Galactic spiral arms, including radial migration of stars, as well as the influence of the Galactic bar on the disc, and thus the disc’s dynamical evolution. It will also shed light on the chemical composition of stars in spiral arms and the role of these structures in shaping the stellar populations over time.

Appendix A: Galaxy models: understanding the Milky Way guiding space features

A.1. Model I: spiral galaxy model

In order to explore the nature of the large-scale overdensities that we discovered in the guiding space of the Milky Way, we present an analysis of two different models of the Milky Way-type galaxies. In particular, to disentangle the perturbations of the guiding phase-space caused by the spiral arms and by the bar, we analyze a model of a multi-arm spiral galaxy (Model I) and a model with a bar and lack of spiral arms (Model II).

Model I is an N-body/hydrodynamical simulation of the stellar-gaseous galactic disc of the Milky Way-type galaxy. The gaseous subsystem is modelled as Smoothed Particle Hydrodynamics (SPH), and the dynamics of the stellar disc is modelled by using a direct particle-particle integration scheme. In order to avoid the change in the bar size due to possible angular momentum exchange between the disc and the halo–bulge system resulting in a slowdown of the bar, we use a rigid galactic potential for spherical components. The importance of a live DM halo has been noted in several works, where the angular momentum exchange between the halo and the disc plays an important role in increasing the bar length over time (Debattista & Sellwood 2000; Athanassoula 2003). However, the impact of live DM halos on the formation and evolution of the spiral arms is not evident. Rigid halo simulations accurately reproduce the radial migration of stars (e.g. Grand et al. 2012, 2013; Vera-Ciro et al. 2014) and are in agreement with theories of spiral structure formation (e.g. Sellwood 2011; Khoperskov et al. 2012a, b; D’Onghia et al. 2013; Sellwood & Carlberg 2019). Thereby we are confident that, at least on the qualitative level, our Model I is a reasonable guide for understanding the Milky Way spiral arms kinematics. In our simulation, the number of particles is $2^{21}$ and $2^{22}$ for stars and gas respectively, and the softening length is about 40 pc for both components. The generation of the model initial equilibrium follows an iterative method of the Jeans equation solution (Khoperskov et al. 2012a). The simulation was performed with a direct GPU N-body/SPH code which provides a very high accuracy of the numerical integration (Khoperskov et al. 2011). Once we select stars in the guiding space of the shocks in a weak spiral potential (Wada & Koda 2004; Khoperskov et al. 2011). Once we select stars in the guiding space features (see Fig. A.1g) we calculate the radial velocity distribution (see Fig. A.1h). For this model and for the observed SDS structures, error bars are determined using the standard deviation of the measurements. The distributions show that the stars associated with spiral arms move inwards (negative radial velocity). This systematic motion explains the mean radial velocity of stars in the spiral arms and their skewed distribution profile (see Fig. A.1h). This result is further evidence that stellar density structures with similar kinematics (SDS 1, 3, 4, 6) correspond to the spiral arms of the Milky Way. In Model I, the spiral structure is a slowly rotating pattern with a corotation outside 10 kpc, where a systematic outward motion (positive radial velocity) of stars is observed in agreement with the density wave theory.

A.2. Model II: barred galaxy model

Model II is a purely collisionless N-body simulation of a composite disc galaxy with live dark matter halo with a total number of particles of $10^7$ for stars and $0.5 \times 10^7$ for dark matter. For the N-body system integration, we used our parallel version of the TREE GRAPE code with multi-thread usage under the SSE and AVX instructions. The tolerance parameter of the tree-code is $\Theta = 0.7$, and for smoothing we use a Plummer potential with 50 pc. For the time integration, we used a leapfrog integrator with a fixed step size of 0.2 Myr. This simulation was previously used to reproduce the morphology of the metal-rich and metal-poor stellar populations in the Milky Way bulge (Fragkoudi et al. 2017, 2018), to understand the origin of the phase-space spirals in isolated Milky Way-type galaxies (Khoperskov et al. 2019), and to explain the ridges in the $R-V_\phi$ plane of the Milky Way (Martinez-Medina et al. 2019; Fragkoudi et al. 2019). In this work we refer in our analysis to the snapshot at 4 Gyr from the beginning of evolution, when no prominent spiral structure is seen, and the bar is the dominant non-axisymmetric structure perturbing the phase-space of the simulated galaxy (see Fig. A.2a).

In Fig. A.2 we show the density distribution of stars in both spatial and guiding space where two prominent quasi-circular distinct features appear in the guiding space. The motion of a star in a galactic plane is described by radial ($v_\phi$ – epicyclic frequency) and angular oscillation ($\Omega$ is the rotation around the galactic centre). To confirm that these overdensities are related to the bar resonances we measure the orbital frequencies ($\Omega, k$) (Binney & Tremaine 1987; Binney & Tremaine 1987; Ceverino & Klypin 2007; Ceverino & Klypin 2007; Hallett et al. 2018) of all particles over a 1 Gyr period around 4 Gyr. Each of the bar resonances is characterized by a certain value of $F = (\Omega - \Omega_{bar})/\kappa$ (e.g. for the bar corotation $F = 0$, and for inner (ILR) and outer Lindblad (OLR) resonances $F = -0.5$ and 0.5 respectively). In Fig. A.2c the overall distribution peaks at the ILR, which is expected for a galaxy with a strong bar, while the OLR is rather weak but slightly stronger than the corotation. The coloured lines show the frequency ratios for stars associated with two prominent features in the guiding phase-space where the inner ring-like structure frequency ratio peaks at corotation (blue) and the outer ring consists in the OLR stars (red). Therefore, the two features we found in the guiding space of the barred galaxy correspond to the corotation and the OLR, or, in other words, the main bar resonances are imprinted in the guiding space as large-scale overdensities. Stellar density distributions and radial velocity maps of stars at the main bar resonances in guiding and spatial scales are presented in Fig. A.2d–h.

Fig. A.1. Milky Way-type galaxy simulation (Model I) showing the behaviour of spiral arms. Panels a and b: face-on stellar surface density in spatial coordinates and in the guiding phase-space, respectively. Panel c: face-on surface density of gas. Panel d: same as (b), but with the colored lines depicting the position of four spiral arms features. Panel e: spatial distribution of star particles associated with the spiral-arm features detected guiding space. Colours of points correspond to the colour of lines in (d). Panel f: gas surface density distribution with a position of stellar spiral arms overlapped. Panel g: zoom-in of the guiding space containing two prominent spiral arms highlighted by the colored lines. Panel h: distribution of the mean radial velocity in the zoomed-in region of the guiding space where the contours show the spiral arm location. Panel i: distribution of the radial velocities of stars in four spiral arms identified in frames (d) and (e) where the spiral arm stars have skewed distribution with negative mean values. The errors in the radial velocity measurements are determined from the scatter around the mean value, using the standard deviation of the measurements. The kinematical features presented here confirm that the structures with similar kinematics found in the guiding space of the Milky Way are the spiral arms.

where stars that are trapped at the bar resonances cover a large area across the disc. The radial velocity distribution along the bar corotation region is roughly symmetric, and the variations in the mean value are caused by sequential gain and loss of angular momentum, while there are no net changes in angular momentum over a long period of time (Ceverino & Klypin 2007). At the bar OLR stars librate around the 2 : 1 closed periodic orbits that correspond to the $x_1(1)$ and $x_1(2)$ families, which contribute to creating the asymmetry in radial velocity along the OLR (Fragkoudi et al. 2019). These changes in the radial velocities are imprinted in the radial velocity distribution for stars at the resonances (see Fig. A.2i); in particular, for a disc region similar to that available in the Milky Way ($|X| < 5$ kpc and $Y < 0$), the mean radial velocity is negative and the distribution spreads over a wide range of values. At the OLR, the radial velocity distribution is dominated by stars on $x_1(1)$ orbits

Fig. A.2. Milky Way-type galaxy simulation (Model II) showing structures near the bar resonances. Panel a: face-on map of the stellar surface density. Panel b: stellar surface density in the guiding space. Two distinct quasi-circular overdensities appear close to the end of the bar and in the outer disc indicated by blue and red circles, respectively. Panel c: spectral analysis of orbits of stars where the fraction of stars with different $F = (\Omega - \Omega_{\text{bar}})/\kappa$ ratio is shown for all disc stars (black) and stars between the blue and red circles in frame (b). Frequency ratios of $-0.5$, $0$, and $0.5$ correspond to the main resonances of the bar, the outer Lindblad, corotation, and inner Lindblad resonances, respectively. Panel d: guiding space density distribution of stars at the bar corotation ($|F| < 0.05$) and at the OLR ($|F| = 0.5 < 0.05$). Panel e: density distribution of stars corotating with the bar in spatial coordinates. Panel f: density distribution of stars at the bar OLR in spatial coordinates. Panel g: mean radial velocity distribution of all stars in the guiding space. Panel h: mean radial velocity distribution of stars at the bar corotation and the OLR in the guiding space. Panel i: distributions of the radial velocities of stars at the bar corotation (blue) and at the OLR (red).

which have positive radial velocities and, on average, this OLR patch moves outwards (positive radial velocity). In Fig. A.2i the error bars in the radial velocity distributions are from comparing 20 simulation snapshots within a ±0.5 Gyr range, using the standard deviation of the measurements. The phase-space and kinematical features that we found for stars at the resonances are in qualitative agreement with those we discovered in the Milky Way disc by analysing the Gaia DR2 (see Fig. 2). Therefore, we confirm that the SDS 2 is likely to be associated with the corotation, while the SDS 5 corresponds to the OLR of the bar.
Appendix B: Guiding space analysis

To explore the physical properties of the features we find in the guiding coordinate space of the Milky Way, we first select stars associated with these structures in the guiding space and plot their distribution in the physical space. For each guiding space overdensity we select stars that have a guiding radius not further than 200 pc from the mean value for a given azimuthal position. In Fig. B.1, we show the (X, Y) maps of the fraction of these selected stars, for each structure, relative to the total number of stars at the same location. These density maps clearly show that the physical location of the recovered structures spans a very large area from the inner 5 kpc region to the outer disc at 11 kpc. A notable feature is that the amplitude of each structure is about 5−12% relative to the total stellar density at a given location.

To place all structures in the Galactic plane, we estimate their mean location from Fig. B.1 by using Gaussian fitting. In particular, we fit the density distributions (see Fig. B.1) along the galactocentric radial direction with 1D Gaussian models. The result of this procedure is overplotted in Fig. B.1, where we also show the width of the structures, calculated as the 1σ dispersion in positions along the radial direction. This width slightly varies along the SDS, and for the different structures, changing from 0.5 kpc, for the innermost spirals, up to ≈2 kpc for the Perseus arm beyond the solar vicinity. The thickness may seem significant, but it must be noted that no selection on age has been made, and our sample therefore includes stars with different kinematics, some of them having large epicyclic motions. Large empirical scatter between different tracers of spiral arms has also been found in nearby spiral galaxies (Tamburro et al. 2008; Foyle et al. 2011; Schinnerer et al. 2013) making spiral arms rather wide for stars of different populations.

Fig. B.1. Amplitude of the stellar density structures causing the large-scale overdensities in the Milky Way phase-space in GRV2. Each frame depicts a fraction of stars corresponding to different guiding space features in the entire Gaia DR2 footprint.
