(Dated: May 29, 2013)

The merger of black hole-neutron star binaries can eject substantial material with the mass \( \sim 0.01-0.1M_\odot \) when the neutron star is disrupted prior to the merger. The ejecta shows significant anisotropy, and travels in a particular direction with the bulk velocity \( \sim 0.2c \). This is drastically different from the binary neutron star merger, for which ejecta is nearly isotropic. Anisotropic ejecta brings electromagnetic-counterpart diversity which is unique to black hole-neutron star binaries, such as viewing-angle dependence, polarization, and proper motion. The kick velocity of the black hole, gravitational-wave memory emission, and cosmic-ray acceleration are also discussed.

I. INTRODUCTION

Black hole (BH)-neutron star (NS) binary coalescences are among the prime sources of gravitational waves (GWs) for ground-based detectors, such as Advanced LIGO, Advanced Virgo, and KAGRA [1,3]. GWs from BH-NS binaries will enable us to probe the supranuclear-density matter [4,5] and cosmological expansion [6] via the NS tidal effect even without electromagnetic (EM) observation. The imprint of the NS tidal effect is the most prominent when the NS is disrupted outside the BH innermost stable circular orbit [7,8]. If tidal disruption occurs outside it, a hot and massive remnant disk may be formed around a remnant BH. Such a system could drive an ultra-relativistic jet, and therefore BH-NS binaries are also important as possible progenitors of short-hard gamma-ray bursts (GRBs) [9].

Mass ejection from the BH-NS merger also has a long history of theoretical investigation [10], and has recently been getting a lot more attention. One of the most important reasons is the pressing necessity to understand EM radiation from, or EM counterparts to, the BH-NS merger. A variety of EM counterparts will be accompanied by the mass ejection from the merger of binary compact objects including NSs [11,12]. Simultaneous detection of EM radiation with GWs are indispensable for confident GW detection and accurate localization of the GW sources.

In this Letter, we explore possible signatures of mass ejection from the BH-NS merger based on our recent numerical-relativity simulations. Numerical relativity is a unique tool to understand the merger of binary compact objects. Numerical-relativity community has been focusing primarily on GW emission and disk formation for the BH-NS merger (see [13] for reviews), and is just beginning to explore mass ejection from the BH-NS merger [8,14]. Whereas characteristic properties of ejecta such as the mass and energy are reported in these works, observational implication of the ejecta is not fully understood yet. In particular, ejecta from the BH-NS merger shows significant anisotropy, and thus EM counterparts could show significant differences from ones by nearly-isotropic ejecta from the NS-NS merger [17,18].

II. SIMULATION

Our BH-NS models are chosen so that the mass ratio, BH spin, and NS equation of state (EOS) are systematically varied. We fix the NS mass, \( M_{\text{NS}} \), to be a representative value \( 1.35M_\odot \) of observed NS-NS binaries [19]. The mass ratio of the BH to NS, \( Q \), is varied from 3 to 7, where \( Q \gtrsim 5 \) may correspond to a typical BH mass in low-mass X-ray binaries [20]. The nondimensional spin parameter of the BH (the spin divided by the mass squared), \( \chi \), is chosen between 0 and 0.75. In this study, we focus on cases in which the BH spin is aligned with the orbital angular momentum. The NS EOS are modeled by the same piecewise polytropes as those described in [17] (see also [21]). Methods for computing initial conditions are described in [8,22].

Our simulations are performed in full general relativity with SACRA [23]. Improvements to previous simulations are summarized as follows (see also [17]). First, we extend computational domains so that we can track long-term evolution of ejecta. Specifically, we solve hydrodynamics equations within the edge length of \( \sim 1500 \) km, and thus we can track ejecta motion up to \( \sim 10 \) ms taking the fact that the ejecta velocity is usually smaller than 0.5c. Asymptotic properties such as the velocity and kinetic energy would not be correctly estimated if we measure them in a near zone. Hence, the large com-
The rest-mass density ($\rho$) profiles of ejecta as an unbound material overplotted with the velocity at $\approx 10$ ms after the merger for $Q = 5$, $\chi = 0.75$, and H4 EOS model. III. MASS EJECTION

When the NS is disrupted by the BH tidal field, a one-armed spiral structure, called as the tidal tail, is formed around the BH. Although a large part of the tail eventually falls back onto the remnant disk and BH, its outermost part obtains a sufficient angular momentum and kinetic energy to become unbound via hydrodynamic angular momentum transport processes. Dynamical mass ejection from the BH-NS merger is driven dominantly by this tidal effect. We also find that some material in the vicinity of the BH becomes unbound when the tidal tail hits itself as it spirals around the BH. This ejection may be ascribed to the shock heating, but this shock-driven component is always subdominant.

Ejecta exhibits a crescent-like shape as depicted in Fig. 1 in most cases. Such a nonaxisymmetric shape arises because the sound-crossing timescale is shorter than the orbital period at the onset of tidal disruption. Furthermore, ejecta spreads dominantly in the equatorial plane, and expands only slowly in the direction perpendicular to the equatorial plane (hereafter, the $z$ direction). The reason for this is that the ejection is driven mainly by the tidal effect, which is most efficient in the equatorial plane. Thus, a portion of circumferential material will be subsequently swept by the ejecta. A typical half opening angle of the ejecta around the equatorial plane is $\theta_{\text{ej}} \approx 1/5$ radian, and this implies that the ejecta velocity in the equatorial plane $v_{\parallel}$ is larger by a factor of $1/\theta_{\text{ej}} \approx 5$ than that in the $z$ direction $v_{\perp}$. Here, $v_{\parallel}$ may be identified with the radial velocity, and the azimuthal velocity should become negligible soon after the ejection due to the angular momentum conservation. Indeed, azimuthal velocity is very small in Fig. 1. Aside from the ejecta itself, the region above the remnant BH is much clearer than that for the NS-NS merger, and thus the baryon-loading problem of GRB jets may be less severe.

The ejecta mass $M_{\text{ej}}$ depends on binary parameters and NS EOSs, and are typically in the range of $\sim 0.01$–$0.1 M_\odot$ when the tidal disruption occurs and the disk mass $M_{\text{disk}}$ exceeds $\sim 0.1 M_\odot$. Important values are shown in Table I. The value of $M_{\text{ej}}$ is generally large when...
the NS EOS is stiff and the NS radius is large for fixed values of $Q$ and $\chi$, because the mass ejection is driven primarily by the tidal effect. This dependence on the NS EOS and radius is opposite to the case of the NS-NS merger in general relativity, where rapid rotation and oscillation of a remnant massive NS drive ejection [17, 18]. We speculate that ejecta from the BH-NS merger might account for a substantial portion of the $r$-process nucleosynthesis (see also below) compared to that from the NS-NS merger if the realistic NS EOS is stiff, and vice versa. When the NS is not disrupted prior to the merger, the ejecta mass is negligible for current astrophysical interest. The ejecta mass is always smaller than the disk mass, and a relation $M_{\text{ej}} \approx 0.05 - 0.2 M_{\text{disk}}$ approximately holds for a wide range. When the disk and ejecta are very massive, it seems that $M_{\text{ej}}$ can be a larger fraction of $M_{\text{disk}}$ than this relation indicates.

The ejecta from the BH-NS merger has a bulk linear momentum, $P_{\text{ej}}$, and resulting large bulk velocity $v_{\text{ej}} \equiv P_{\text{ej}}/M_{\text{ej}} \sim 0.2c$, in a particular direction. These bulk linear momentum and velocity would essentially vanish for nearly spherical ejecta such as one from the NS-NS merger. The value of $v_{\text{ej}} \sim 0.2c$ depends only weakly on the binary parameters and NS EOS as far as the mass ejection is substantial.

Typical values of kinetic energy $T_{\text{ej}}$ are in the range $\sim 5 \times 10^{50} - 5 \times 10^{51}$ erg. The average velocity of the ejecta $v_{\text{ave}} \approx (2T_{\text{ej}}/M_{\text{ej}})^{1/2}$ is typically $0.25 - 0.3c$, and is naturally larger than $v_{\text{ej}}$. The contribution of $v_{\bot}$ to $T_{\text{ej}}$ is smaller by a factor of $\theta_{\text{ej}}^2$ than that of $v_{\parallel}$, and thus a relation $v_{\text{ave}} \approx v_{\parallel}$ holds. For an axisymmetric outflow truncated at an opening angle $\varphi_{\text{ej}}$, a relation $v_{\parallel} / v_{\parallel} \approx \sin(\varphi_{\text{ej}}/2)/(\varphi_{\text{ej}}/2)$ should hold, and thus the ejecta opening angle in the equatorial plane is estimated to be $\varphi_{\text{ej}} \approx (0.7 - 1.3)\pi$ radian. This is consistent with Fig. [1].

IV. DISCUSSION

In this section, we discuss possible consequences of the anisotropic ejecta from the BH-NS merger in chronological order as possible. For convenience, we introduce $M_{1.35} \equiv M_{\text{NS}}/1.35 M_\odot$, $A_5 \equiv (1 + Q)/(1 + 5)$, $M_{\text{ej},0.03} \equiv M_{\text{ej}}/0.03 M_\odot$, $v_{\text{ej},0.2} \equiv v_{\text{ej}}/0.2c$, $v_{\text{ave},0.3} \equiv v_{\text{ave}}/0.3c$, $\theta_{\text{ej},i} \equiv \theta_{\text{ej}}/(1/5)$, and $\varphi_{\text{ej},i} \equiv \varphi_{\text{ej}}/\pi$.

A. Kick velocity of the black hole

The remnant BH should receive back-reaction from the ejecta with $M_{\text{ej}}$ and $v_{\text{ej}}$, and obtain substantial “ejecta kick” velocity [24]. The total mass of the remnant BH and surrounding disk is determined approximately by the mass of the binary at infinite separation $m_0 = (1 + Q)M_{\text{NS}}$, neglecting $M_{\text{ej}}$ and energy carried by GWs $\sim 0.05 m_0 c^2$. Thus, the ejecta kick velocity of the remnant BH-disk will be

$$v_{\text{kick}} \approx \frac{M_{\text{ej}}}{m_0} v_{\text{ej}} = 220 \text{ km s}^{-1} M_{\text{ej},0.03} v_{\text{ej},0.2} M_{1.35}^{-1} A_5^{-1}.$$  

(1)

This value is larger than escape velocity of globular clusters and dwarf galaxies for many cases, and can exceed that of small galaxies under suitable conditions [25].

The ejecta kick velocity, $v_{\text{kick}}$, can be larger than the kick velocity due to GW radiation reaction. Specifically, the GW kick velocity is at most $\sim 100 \text{ km s}^{-1}$ when the NS is disrupted prior to the merger, even if the BH spin is misaligned [8, 26, 27]. The reason for this is that the linear momentum is radiated most efficiently when the binary is about to merge, and therefore earlier disruption significantly suppresses the GW kick velocity. Thus, the ejecta kick velocity can dominate the velocity of the remnant when tidal disruption is prominent.

B. Gravitational-wave memory

Because the ejecta and remnant BH-disk travel in the opposite direction after the merger, nonoscillatory GW emission, i.e., GW memory, is expected. Assuming that the remnant mass $\approx m_0$ is much larger than $M_{\text{ej}}$, magnitude of this (linear) ejecta memory is given approximately by [28]

$$\delta h \approx \frac{2GM_{\text{ej}} v_{\text{ej}}^2}{c^4 D} = 1.1 \times 10^{-24} M_{\text{ej},0.03} v_{\text{ej},0.2}^2 D_2^{-1},$$  

(2)

where $D \equiv D_2 \times 100$ Mpc is a distance from the binary to the observer. Taking the fact that the expected rise time of ejecta memory is much shorter than the inverse of frequency at which ground-based detectors are most sensitive, ($\sim 100 \text{ Hz}$)$^{-1}$, it may be possible to detect ejecta memory by Einstein Telescope [29] if the ejecta is massive as $\gtrsim 0.1 M_\odot$. Such a possibility is not negligible if the BH spin can be very large [13].

The ejecta memory as well as GWs from the binary coalescence can be strongest in the $z$ direction. Such memory would easily be distinguished from linear memory from GRB jets [30] and nonlinear memory from coalescence GWs [31], which are very weak in the $z$ direction, if we observe the binary from this direction.

C. Macronova/kilonova

The macronova a.k.a. kilonova is quasithermal radiation from the ejecta heated by the radioactive decay of $r$-process elements [32, 34]. Although properties of $r$-process elements such as opacities are still uncertain so that accurate predictions are difficult [35, 36], the macronova/kilonova is one of the most promising EM counterparts to the BH-NS merger.

Peak values of the macronova/kilonova are estimated when the diffusion timescale becomes equal to the dynamical timescale, which is essentially the time after the
merger. Assuming random walks of photons in spherical ejecta, the peak time is estimated to be 
\[ t_{\text{peak}} \approx (3\kappa M_{\text{ej}}/4\pi c v_{\text{ave}})^{1/2} = 8 \text{ day} \] 
where \( \kappa = 10 \, \text{g}^{-1} \, \text{cm}^2 \) is the opacity. If a fraction \( f = f_{-6} \times 10^{-6} \) of \( M_{\text{ej}} \) is radiated, the peak luminosity is expected to be 
\[ L_{\text{peak}} \approx f M_{\text{ej}} c^2/t_{\text{peak}} = 7 \times 10^{40} \text{ erg s}^{-1} \] 
and the temperature at the peak is 
\[ T_{\text{peak}} \approx (L_{\text{peak}}/4\pi v_{\text{ave}}^2 t_{\text{peak}})^{1/4} = 1200 K \]

The emission could be modified by ejecta geometry for the BH-NS merger. We approximate ejecta geometry by an axisymmetric cylinder with \( v_{\parallel} \) and \( v_{\perp} \) in the radial and \( \phi \) directions, respectively, and truncate at an opening angle \( \varphi_{\text{ej}} \). Assuming that photons escape from the \( z \) direction due to a short distance, the peak time is estimated as

\[ t_{\text{peak}} \approx \left( \frac{\kappa M_{\text{ej}} v_{\perp}}{e \varphi_{\text{ej}} v_{\parallel}} \right)^{1/2} \]
\[ = 4 \text{ day} \]

Accordingly, the peak luminosity is

\[ L_{\text{peak}} \approx \frac{f M_{\text{ej}} c^2}{t_{\text{peak}}} \]
\[ = 1.4 \times 10^{41} \text{ erg s}^{-1} \]

and finally the temperature at the peak is

\[ T_{\text{peak}} \approx \left( \frac{L_{\text{peak}}}{\varphi_{\text{ej}} v_{\parallel} v_{\perp}} \right)^{1/4} \]
\[ = 3000 K \]

These rough estimates suggest that characteristics of the macronova/kilonova will be modified by a factor of a few.

Directional dependence is important for the macronova/kilonova of the BH-NS merger. In particular, the flux will differ by a factor of \( \approx 1/\theta_{\text{ej}} \approx 5 \) for different viewing angles at \( t_{\text{peak}} \). Specifically, the radiation will be dim if we are located in the equatorial plane. The time evolution of light curves will also differ, because the diffusion timescale is different for different viewing angles. Although atomic line structures of \( r \)-process elements will be blended due to the variety of elements and energy levels, observation might be possible from the \( z \) direction, for which the line broadening is not severe due to the small velocity, \( v_{\text{perp}} \), if some prominent lines are isolated. Blueshifts of lines are also small in the \( z \) direction. In addition, linear polarization up to \( \approx 4-5\% \) is expected for an aspherical photosphere observed in the equatorial plane.

**D. Synchrotron radio flare**

Blast waves will develop between the ejecta and interstellar medium (ISM) as the ejecta travels in the ISM. If electrons are accelerated to nonthermal velocity distribution and magnetic fields are amplified behind the blast waves in a similar manner to supernova remnants and GRB afterglows, synchrotron radio flares should arise. The synchrotron radio flare is also one of the most promising EM counterparts.

The peak time of the flare is the time at which the ejecta accumulates the mass comparable to its own from the ISM with density \( n_{\text{H}} = n_{\text{H},0} \times 1 \, \text{cm}^{-3} \) and begins to be decelerated. The deceleration radius is given by 
\[ R_{\text{dec,s}} = (3M_{\text{ej}}/4\pi n_{\text{H}})^{1/3} = 0.7 \, \text{pc} \]

The ejecta from the BH-NS merger is not spherical, and can accumulate only a small portion of the ISM within a fixed radius. Thus, the ejecta has to travel a longer distance \( R_{\text{dec}} > R_{\text{dec,s}} \) to be decelerated than spherical ejecta. Here, we assume that values of \( v_{\parallel} \) and \( v_{\perp} \) do not change significantly before the deceleration. This would lead to constant values of \( \theta_{\text{ej}} \) and \( \varphi_{\text{ej}} \) before the deceleration, which is expected to occur at

\[ R_{\text{dec}} \approx R_{\text{dec,s}} \left( \frac{\pi/2}{\theta_{\text{ej}}} \right)^{1/3} \left( \frac{2\pi}{\varphi_{\text{ej}}} \right)^{1/3} \]
\[ = 1.7 \, \text{pc} \]

and therefore the peak time is

\[ t_{\text{dec}} = \frac{R_{\text{dec}}}{v_{\parallel}} = 18 \text{ yr} \]

The peak time should be closer to (but still longer than due to the energy conservation) \( t_{\text{dec,s}} \) if the ejecta approaches a spherical state. The reality may exist between these two limits. We left precise modelings of geometry evolution for the future study.

The peak luminosity and flux of the flare do not depend on geometry as far as ejecta evolves adiabatically. The reason for this is that the peak time is still the time at which the ejecta accumulate \( M_{\text{ej}} \) from the ISM, and thus the number of emitting electrons and their characteristic frequency do not change. Directional dependence of the flare as well as that of the macronova/kilonova is worth studying.

**E. Proper motion of radio images**

Because the ejecta moves with \( v_{\text{ej}}, \) radio observation will be able to detect the proper motion of radio images in the timescale of \( t_{\text{dec}} \) in addition to expansion of images. A characteristic travel distance may be given by 
\[ R_{\text{dec}}(v_{\text{ej}}/v_{\text{ave}}) \]

Averaging over random distribution of
ejecta direction halves the projected distance. In reality, however, GW observation may be biased toward the z axis, and then the biased average could be larger. We expect the projected proper motion of radio images to be $O(1)$ pc around the synchrotron radio flare peak. This implies that the radio image is expected to move $O(1)$ mas for a BH-NS binary at $O(100)$ Mpc. Current radio instruments can resolve this angle [40].

The proper motion will give us a way to distinguish the BH-NS merger from the NS-NS merger, because proper motion of radio images should be much smaller for the latter, whereas expansion of images should be common to two merger types. It is not easy to distinguish between BH-NS and NS-NS binaries only from GW observation, especially when the BH is less massive [41]. Thus, information provided by EM counterparts is also useful for the determination of merger types [42,43].

**F. Cosmic-ray acceleration**

Physical condition of the ejecta is expected to be similar to that of a supernova remnant. This implies that the cosmic-ray (CR) acceleration will occur in the remnant of ejecta from the BH-NS merger via diffusive shock acceleration [44,45], as well as the NS-NS merger. The proper motion will give us a way to distinguish the BH-NS and NS-NS binaries only from GW observation, especially when the BH is less massive [41]. Thus, information provided by EM counterparts is also useful for the determination of merger types [42,43].

\[
\varepsilon_{\text{max}} = 2.4 \times 10^{18} \text{ eV} Z \frac{1}{3} M_{\text{ej},0.03}^{1/3} \nu_{\text{ave},0.3}^{1/2} B_{-1}^{1/6} \theta_{i}^{2/3} \rho_{\text{ej},i}^{-1/3},
\]

where we adopt $R = R_{\text{dec}} \theta_{\text{ej}}$. The higher energy than that for supernova remnants primarily owes to the faster ejecta velocity.

CRs from the galactic BH-NS merger could explain observed CRs above the knee region up to the ankle region. Taking the fact that ejecta kinetic energy is comparable to that of supernova remnants and comparing galactic BH-NS merger rate estimation $\sim 10^{-7} - 10^{-4} \text{ yr}^{-1}$ [47] with the galactic supernova rate $\sim 0.01 \text{ yr}^{-1}$, the CR energy above the knee can be explained. Evidently, acceleration, propagation, and galactic confinement of CRs including nuclei have to be investigated in more detail.

Acceleration of heavy elements like irons to even an ultra-high energy $\gtrsim 10^{20} \text{ eV}$ are also possible for massive ejecta $\gtrsim 0.2 M_\odot$ such as ones reported in [15]. Although an energetics constraint is not assured, observed energy of ultra-high energy CRs [48] is marginally consistent within the uncertainty of merger rate estimation. Assuming that a fraction $\varepsilon_{\text{CR}} \equiv \varepsilon_{\text{CR},-1} \times 0.1$ of ejecta kinetic energy averaged over BH-NS binary distribution $\langle T_{\text{ej},i} \rangle \equiv \langle T_{\text{ej},51} \rangle \times 10^{51} \text{ erg}$ is converted to CR energy, the required merger rate is approximately $\varepsilon_{\text{CR},-1} \langle T_{\text{ej},51} \rangle^{-1} \text{ Mpc}^{-3} \text{ Myr}^{-1}$, where 1 Mpc$^{-3}$ Myr$^{-1}$ is the “high” estimation [47].
