INTRODUCTION

A coronary fistula is an abnormal connection between the coronary artery and another vessel or cardiac chamber and is occasionally identified during coronary angiography (CAG). Although a coronary fistula can be visualized during CAG, in this case, after the angiography, the coronary fistula could not be detected. Coronary computed tomography angiography (CCTA) after percutaneous coronary intervention (PCI) revealed a micro-fistula from the RCA to the right ventricle. Our report represents an abrupt angiographical change due to a tiny coronary fistula.

CASE REPORT

An 82-year-old female patient was scheduled for CAG as a follow-up for a previous coronary artery bypass (CAB) and coronary stent implantation that were performed without post-operative complications. She had undergone the CAB, which involved the left internal thoracic artery to mid-left descending artery and radial artery to left circumflex artery, because of angina of effort in 1998. New-onset chest discomfort at rest occurred in 2013 and total occlusion at the mid-right coronary artery (RCA) was detected, followed by the implantation of an everolimus-eluting stent (Xience-Xpedition® 3.25/38 mm; Abbott Vascular, Chicago, IL, USA).

CAG at 9 months after stenting revealed a new coronary in-stent stenosis at the mid-RCA with significant myocardial ischemia, followed by PCI. Frequency-domain optical coherence tomography (FD-OCT) was performed with manual rapid contrast flushing (10 mL/sec) after the coronary wire was passed through the stenosis to determine lumen size and tissue characteristics. The angiography at OCT resembled an oozing rupture of the coronary vessel (Supplementary Fig. 1A and Supplementary Movie 1 in the online-only Data Supplement); however, the patient was asymptomatic and her vital signs were stable. Echocardiography was performed to determine if cardiac tamponade had been caused by the coronary perforation, but no cardiac effusion was identified. CAG was repeated immediately, with a normal speed injection (5 mL/sec), but the repeat CAG did not show any abnormalities (Supplementary Fig. 1B and Supplementary Movie 1 in the online-only Data Supplement).

FD-OCT showed partial dissection of the coronary vessel, but no signs of vessel perforation, therefore, we decided to con-
Micro-fistulas, similar to this case, could be the pre-phase of a cause increased flow may occur even for asymptomatic fistulas. Because they can increase in size as the children grow and be detected with CAG [3]. For children, these fistulas are monitored during CAG; however, they are usually large and visible. The majority of coronary fistulas are congenital and some coronary fistulas are acquired after infection, trauma, and iatrogenic injury, however, many minute fistulas can remain undetectable [1]. Based on this patient's previous history of CAB graft surgery, it is possible that this coronary fistula was a result of that procedure. Coronary fistulas are typically associated with CTA, although in this case the lumen was relatively long and smooth. Iatrogenic coronary fistulas have been reported to show relatively short routes with an irregular lumen [2], therefore, we speculated that this was a congenital tiny fistula.

This case was characterized by abrupt angiographical change, even though the change did not occur in cases with typical coronary fistulas. This case is unique because the angiographical findings changed immediately after previous imaging. We speculated that the cause for these abrupt changes was attributable to the difference in the amount of contrast through the coronary fistula to the right ventricle. A typical coronary fistula is relatively large in diameter, therefore, a large amount of contrast through the fistula could visualize the route. For cases with tiny fistulas, a small amount of contrast is insufficient for visualizing the route. Interestingly, in this case, the contrast draining into the right ventricle through the tiny fistula could only be visualized with a high pressure injection.

This case showed that CCTA was useful for detecting the origin of the micro-coronary fistula, which connected the RCA to the RV. Many coronary fistulas are small and are accidentally detected with CAG [3]. For children, these fistulas are monitored because they can increase in size as the children grow and because increased flow may occur even for asymptomatic fistulas. Micro-fistulas, similar to this case, could be the pre-phase of a large fistula that could be seen on CAG. Larger coronary fistulas may lead to angina pectoris because of the coronary steal phenomenon that necessitates surgical repair. Tuncer et al. [4] revealed that micro-coronary fistulas were detected via angiography, but they could not demonstrate the fistula drainage location into because additional imaging modalities, such as CTA or transesophageal echocardiography, were not performed. Based on these results, CCTA may reveal an immature fistula undetected by routine CAG and may be a more sensitive modality than CAG for follow-up.

Coronary fistulas have increased as children age [3], and if these large fistulas remain untreated, angina or heart failure could occur in 63% of these patients during adulthood [5]. In this case, fractional flow reserve showed no RCA ischemia after PCI. The reason that ischemia was not identified was attributable to adequate dilatation of the RCA lesion and less steal flow draining through the coronary fistula into the RV. Several microvessels maintain microcirculation in the myocardium but they are rarely revealed in clinical examination. In conclusion, asymptomatic fistulas should be monitored because of the possibility of fistula enlargement, and CCTA is a useful approach for identifying these small fistulas.

**DISCUSSION**

This paper reports a micro-coronary fistula from the RCA to the RV that was revealed only when CAG with high-pressure injection was performed. Fistulas are occasionally encountered during CAG; however, they are usually large and visible. The majority of coronary fistulas are congenital and some coronary fistulas are acquired after infection, trauma, and iatrogenic injury, however, many minute fistulas can remain undetectable [1]. Based on this patient's previous history of CAB graft surgery, it is possible that this coronary fistula was a result of that procedure. Coronary fistulas are typically associated with CTA, although in this case the lumen was relatively long and smooth. Iatrogenic coronary fistulas have been reported to show relatively short routes with an irregular lumen [2], therefore, we speculated that this was a congenital tiny fistula.

This case was characterized by abrupt angiographical change, even though the change did not occur in cases with typical coronary fistulas. This case is unique because the angiographical findings changed immediately after previous imaging. We speculated that the cause for these abrupt changes was attributable to the difference in the amount of contrast through the coronary fistula to the right ventricle. A typical coronary fistula is relatively large in diameter, therefore, a large amount of contrast through the fistula could visualize the route. For cases with tiny fistulas, a small amount of contrast is insufficient for visualizing the route. Interestingly, in this case, the contrast draining into the right ventricle through the tiny fistula could only be visualized with a high pressure injection.

This case showed that CCTA was useful for detecting the origin of the micro-coronary fistula, which connected the RCA to the RV. Many coronary fistulas are small and are accidentally detected with CAG [3]. For children, these fistulas are monitored because they can increase in size as the children grow and because increased flow may occur even for asymptomatic fistulas. Micro-fistulas, similar to this case, could be the pre-phase of a large fistula that could be seen on CAG. Larger coronary fistulas may lead to angina pectoris because of the coronary steal phenomenon that necessitates surgical repair. Tuncer et al. [4] revealed that micro-coronary fistulas were detected via angiography, but they could not demonstrate the fistula drainage location into because additional imaging modalities, such as CTA or transesophageal echocardiography, were not performed. Based on these results, CCTA may reveal an immature fistula undetected by routine CAG and may be a more sensitive modality than CAG for follow-up.

Coronary fistulas have increased as children age [3], and if these large fistulas remain untreated, angina or heart failure could occur in 63% of these patients during adulthood [5]. In this case, fractional flow reserve showed no RCA ischemia after PCI. The reason that ischemia was not identified was attributable to adequate dilatation of the RCA lesion and less steal flow draining through the coronary fistula into the RV. Several microvessels maintain microcirculation in the myocardium but they are rarely revealed in clinical examination. In conclusion, asymptomatic fistulas should be monitored because of the possibility of fistula enlargement, and CCTA is a useful approach for identifying these small fistulas.

**Supplementary Movie Legends**

Movie 1. Coronary angiography with high-pressure injection during optical coherence tomography. Contrast medium, which is likely outside the coronary vessels, can be seen. Coronary angiography with normal injection shows no abnormal findings, immediately after the previous finding.
