OBJECTIVE Awake transforaminal lumbar interbody fusion (TLIF) is a novel technique for performing spinal fusions in patients under conscious sedation. Whether awake TLIF can reduce operative times and decrease the hospital length of stay (LOS) remains to be shown. In this study, the authors sought to assess the differences in clinical outcomes between patients who underwent awake TLIF and those who underwent TLIF under general anesthesia by using institutional experience at the Mayo Clinic and the National Surgical Quality Improvement Program (NSQIP) database.

METHODS Chart review was performed for a consecutive series of patients who underwent single-level minimally invasive surgery (MIS)–TLIF performed by a single surgeon (K.A.I.) at a single institution. Additionally, the NSQIP database was queried from 2016 to 2019 for patients who underwent awake TLIF as well as propensity score–matched patients who underwent TLIF under general anesthesia.

RESULTS A total of 20 patients at Mayo Clinic underwent awake single-level MIS-TLIF. The mean operative time was 122 ± 16.68 minutes, and the mean estimated blood loss was 39 ± 30.24 ml. No intraoperative complications were reported. A total of 96 patients who underwent TLIF (24 awake and 72 under general anesthesia) were analyzed from the NSQIP database. The mean LOS was less in the awake cohort (1.4 ± 1.381 days) than the general anesthesia cohort (3 ± 2.274 days) (p = 0.002).

CONCLUSIONS Evidence from the authors’ institutional experience and national analysis has demonstrated that awake MIS-TLIF is efficient and can reduce hospital LOS.

KEYWORDS awake; anesthesia; minimally invasive; transforaminal lumbar interbody fusion; TLIF; spine
geons have chosen to perform awake TLIF spinal fusions in select patients. Awake MIS-TLIF protocols combine the benefits of both MIS and awake procedures including minimal tissue damage and reduced exposure to anesthet-
ic agents. However, it remains to be shown whether awake MIS-TLIF can reduce operative times and decrease LOS.

The purpose of this study was to assess the differences in clinical outcomes between patients undergoing awake TLIF and those undergoing TLIF with general anesthesia by assessing our institutional experience at Mayo Clinic, as well as national data from the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) registry.

Methods

Institutional Cohort

Chart review was conducted for a consecutive series of patients who underwent single-level MIS-TLIF performed by a single surgeon (K.A.I.) from February 2020 to October 2020. Age, sex, race, BMI, American Society of Anesthesiologists (ASA) class, and preoperative comorbidities were collected for each patient. Additionally, we report outcomes, including procedure time, LOS, estimated blood loss (EBL), and discharge disposition.

Despite its prospective advantages, awake MIS-TLIF is not appropriate for all surgical candidates. Some patient selection criteria should be taken into consideration when performing this operation. We recommend choosing patients without significant obesity or obstructive sleep apnea, as the need for an urgent intubation might be challenging if excessive CO₂ accumulates during the surgery. In addition, patients with claustrophobia or comorbid anxiety may not tolerate the conscious sedation required for the procedure. Those patients may feel uncomfortable during the surgery because of the long periods of prone positioning and the sounds of surgical instruments, which may elevate the heart rate and/or blood pressure.

At our institution, we used 12.5 mg to 15 mg of isobaric intrathecal bupivacaine with or without the addition of intrathecal narcotic (fentanyl or hydromorphone). The drug was administered one level above the level of planned surgical intervention. Prior to administration of the spinal anesthesia, fentanyl and/or 2 mg of midazolam (100 µg) were administered. Intraoperative medication such as dexmedetomidine (0.1–0.2 µg/kg per hour intravenously, as needed), propofol (10–25 µg/kg per minute intravenously, as needed), midazolam, or fentanyl was administered to provide patient comfort during the operation.

National Analysis

The NSQIP database was queried from 2016 to 2019 for all elective procedures with a principal Current Pro-
cedural Terminology (CPT) code of 22612 (“arthrodesis, posterior or posterolateral technique, single level; lumbar with lateral transverse technique, when performed”). Similar to the study by Garcia et al., who used the NSQIP database to study readmissions after TLIF, we excluded procedures that did not use a transverse lateral approach or involved more than one level by excluding admissions that contained additional CPT codes, such as 22614, 22630, 22632, 22633, and 22634. The “ANESTHES” variable in the NSQIP database was used to determine the anesthesia type. We considered procedures with an anesthesia category of epidural, local, monitored anesthesia care/intra-
venous sedation, regional, or spinal anesthesia as awake procedures. Awake patients were matched against patients who had surgery under general anesthesia using 1:3 propensity score matching based on age, sex, race, ASA class, functional status, and comorbidities (diabetes, chronic obstructive pulmonary disease [COPD], heart failure, dyspnea, and hypertension requiring medication).

All statistical analyses were performed using R version 4.1.0 (The R Project). Propensity score matching was performed using the matchit() function from the “MatchIt” package. Univariate analysis comparing awake cases versus matched general anesthesia cases was performed using the table() function from the “arsenal” package. All continuous outcomes were compared using ANOVA tests, and categorical outcomes were compared using the chi-square test.

Results

Institutional Cohort

A total of 20 patients (8 men and 12 women) underwent single-level MIS-TLIF awake spinal fusion at Mayo Clin-
ic. The mean age ± SD of the included patients was 63.6 ± 8.25 years. The mean BMI was 30.76 ± 4.83 kg/m². The level of fusion was L4–5 in 11 patients (55%), L5–S1 in 5 patients (25%), L4–S1 in 2 patients (10%), L3–5 in 1 pa-
tient (5%), and L3–4 in 1 patient (5%). Most patients who underwent awake MIS-TLIF were female (n = 12, 60%), and the majority were White (n = 19, 95%), with 1 African American patient (5%) included. The patient demographic characteristics are presented in Table 1.

Of all 20 patients, 12 presented with preoperative comorbidities, with 9 patients presenting with ≥ 2 simulta-
neous comorbidities. Among the comorbidities, hyperten-
sion (n = 9, 45%) and obesity (n = 9, 45%) were the most prevalent, followed by diabetes mellitus (n = 4, 20%), sleep apnea (n = 4, 20%), and coronary artery disease (n = 2, 10%) (Table 2).

In terms of surgical characteristics, 11 patients (55%) presented with a preoperative ASA class of II, while the remaining 9 patients (45%) presented with an ASA class of III. The mean operative time was 122 minutes, ranging from 98 to 162 minutes. The mean EBL was 39 ml, ranging from 10 to 150 ml. The mean LOS was 1.15 ± 1.25 days, with 7 patients discharged on the same day. All patients were successfully discharged home. The surgical characteristics of all patients are listed in Table 3.

National Analysis

A total of 96 patients were included from the NSQIP database. The mean age of patients was 57.9 ± 14.1 years. The majority of patients were male (n = 65, 67.7%) and predominately White (n = 93, 96.9%). There was no statistical significance between the awake and general anesthesia groups in terms of age, sex, race, and comorbidities (including diabetes, COPD, and hypertension) after matching (Table 4).

The general anesthesia group included 72 patients with

CAD = coronary artery disease; DM = diabetes mellitus; HTN = hypertension.
a mean age of 57.8 ± 13.9 years. Most of these patients were male (n = 49, 68.1%) and White (n = 70, 97.2%). Of those, 6 patients (8.3%) presented with insulin-dependent diabetes, 4 patients (5.6%) had a history of COPD, and 53 patients (73.6%) had a history of hypertension. The awake group included 24 patients with a mean age of 58.3 ± 14.8 years. Most of these patients were male (n = 16, 66.7%) and White (n = 23, 95.8%). Of those, 2 patients (8.3%) presented with insulin-dependent diabetes, 2 patients (8.3%) had a history of COPD, and 16 patients (66.7%) had a history of hypertension.

The mean LOS for the awake group was 1.4 days compared with 2.986 days for the general anesthesia group, and the mean operative time was 143.1 hours for the awake group compared with 175.47 hours for the general anesthesia group. Most of the patients who underwent awake spinal fusion were discharged home (87.5%) with the remaining patients discharged to a rehabilitation center and skilled care facility (4.2% and 8.3%, respectively). No patients from the awake cohort were readmitted within 30 days following the surgery compared with 3 patients (4.2%) who underwent general anesthesia under general anesthesia or with open techniques. While many have hypothesized that awake MIS techniques may offer benefits to patients such as decreased postanesthesia recovery periods and reduced LOS, this has not yet been thoroughly evaluated in the literature. In the current study, we have reported our institutional experience with performing awake MIS-TLIF and also presented a national analysis of recent TLIF cases from the NSQIP registry comparing those performed awake versus those performed under general anesthesia. Our study provides evidence that awake MIS-TLIF can be performed safely with minimal postprocedural complications and reasonable operative times, averaging 122 minutes. Additionally, our national data provide evidence that awake TLIF is associated with decreased hospital LOS compared with TLIF performed under general anesthesia.

Of note, based on our national data on awake TLIF, we did not find that awake TLIF was associated with decreased operative times or reduced readmission rates. This finding could potentially be explained by increased variability in national data from the NSQIP registry compared with our own institutional experience. In our cohort, the range in operative time for awake cases was 96 to 162 minutes. In contrast, the awake TLIF group from the NSQIP database had a range in operative time of 45 to 410 minutes versus a range of 25 to 864 minutes in the matched general anesthesia control group. The significant variability in the NSQIP data may be explained by differing surgeon expertise between centers or differences in reporting quality. This limited our ability to resolve differences in operative times and readmission rates between awake versus general anesthesia cases in our national co-

hort. Additional studies aggregating institutional case series, similar to that reported here, will be needed to better resolve these outcomes.

Several centers have reported data on awake spine surgery with early outcomes demonstrating shorter recovery times and improved perioperative morbidity and mortality.7,11 Additionally, patient-reported outcomes (PROs) are usually better with the awake spinal fusion protocol. Kolcun et al. reported significant improvement in PROs with no pseudarthrosis or implant failure.11 Their results showed that this technique is successful with meaningful improvement in long-term functional status as well as a shorter recovery time, better postoperative analgesia, and less perioperative morbidity and mortality.

One critical benefit to awake TLIFs is conscious sedation, which permits patients to stay conscious and interact with their surgeon throughout intricate steps in the procedure, some of which include manipulating nerve roots that have direct impact on neurological symptoms.7 The limited use of intubation and general anesthesia decreases the need for mechanical ventilation, allowing spontaneous breathing to lower intrathoracic pressure and minimize bleeding during procedures.7 Wang and Grossman reported their experience after performing endoscopic sin-

GA = general anesthesia.
ingle-level MIS-TLIF. Ketamine and propofol were used to sedate the patients. Their results showed that arthrodesis rates are successful when compared with open surgery.  
While PROs and individual complication rates were not captured in the institutional and national data reported here, these represent avenues for future study.

Limitations

While our study offers several new insights into outcomes after awake MIS-TLIF based on both institutional and national data, there are several limitations that are important to acknowledge when interpreting the data. First, we could not include radiological findings in our comparisons as these data are not collected by the NSQIP database. Second, patients who had allergies to anesthetic components included in the awake anesthesia protocol could not be assigned to the awake group. Third, a limited amount of data were available in the NSQIP database for awake MIS-TLIF cases, and outcomes in that group may reflect the experience of a few high-performing centers with significant knowledge of the procedure. The NSQIP database does not allow for distinction between MIS versus open TLIF cases and, hence, both were included in our analysis. Lastly, many studies, including our own, that have investigated the outcomes of awake MIS-TLIF have only studied single-level fusions, with very little data available regarding the effects of multilevel fusions.

Conclusions

Evidence from our institutional experience and national analysis demonstrates that awake MIS-TLIF can be performed safely with no major perioperative complications and may reduce LOS compared with cases performed under general anesthesia.
