Background: We aimed to identify prognostic blood biomarkers using proteomics-based approaches in malignant pleural mesothelioma (MPM).

Methods: Plasma samples from 12 MPM patients were used for exploratory mass spectrometry and ELISA analyses. The significance of secreted protein acidic and rich in cysteine (SPARC) was examined in sera from a Dutch series (n = 97). To determine the source of the circulating SPARC, we investigated SPARC expression in MPM tumours and healthy controls, as well as the expression and secretion from cell lines and xenografts.

Results: Secreted protein acidic and rich in cysteine was identified as a putative prognostic marker in plasma. Validation in the Dutch series showed that the median survival was higher in patients with low SPARC compared with those with high SPARC (19.0 vs 8.8 months; P = 0.01). In multivariate analyses, serum SPARC remained as an independent predictor (HR 1.55; P = 0.05). In MPM tumour samples, SPARC was present in the tumour cells and stromal fibroblasts. Cellular SPARC expression was higher in 5 out of 7 cell lines compared with two immortalized mesothelial lines. Neither cell lines nor xenograft tumours secreted detectable SPARC.

Conclusions: Low circulating SPARC was associated with favourable prognosis. Secreted protein acidic and rich in cysteine was present in both tumour cells and stromal fibroblasts; and our in vitro and in vivo experiments suggest that stromal fibroblasts are a potential source of circulating SPARC.

Malignant pleural mesothelioma (MPM) is an almost invariably fatal, asbestos-related malignancy arising from the mesothelium surrounding the thoracic cavities. Progress in MPM treatment has remained modest, with a median survival varying from 7 months to 2 years (Vogelzang, 2008; Van Meerbeeck et al, 2011). Use of the few treatment options available is guided by traditional prognostic factors such as performance status, histological subtype and stage of disease (Scherpereel et al, 2010; Van Meerbeeck et al, 2011). The use of pemetrexed/cisplatin chemotherapy is associated with a response rate of around 40% and a survival gain of around 3 months (Vogelzang et al, 2003). None of the molecular markers investigated to date is able to accurately predict the course of the disease or the response to therapy. A biomarker, or a combination of biomarkers, that is able to determine prognosis or response to therapy and which is accurate enough to be used for the selection of individual patients is therefore urgently needed. Ideally, a simple blood-based biomarker would be advantageous given its easy accessibility.

There are several blood-based biomarkers that have been shown to have some diagnostic utilities. These include osteopontin, soluble mesothelin-related peptides (SMRP) and more recently, fibulin-3 (Grigoriu et al, 2007; Roe et al, 2007; Schneider et al, 2008; Pass et al, 2012). These diagnostic biomarkers also have a limited prognostic role in MPM, with elevated levels of osteopontin and SMRP showing correlation with shorter survival (Grigoriu et al, 2007; Roe et al, 2008; Schneider et al, 2008). Although the concentration of fibulin-3 in the plasma did not correlate with survival, high levels in effusions were associated with shorter survival (Pass et al, 2012).

Identification of circulating blood-based biomarkers has also been attempted via proteomics-based approaches. Ostroff et al (2012) discovered and validated a panel of serum biomarkers as a non-invasive proteomics-based surveillance tool in the early diagnosis of MPM in patients at high risk for this disease. Using the Selected Reaction Monitoring (SRM) assay technology, Cerciello et al (2013) also identified serum protein-derived candidate biomarker panels for the diagnosis of MPM.

Given the feasibility of biomarker identification using proteomics-based technology and the lack of accurate prognostic biomarkers in MPM, we initially designed an exploratory proteomic study, in which we systematically investigated proteins present in plasma of MPM patients using the isobaric tag for relative and absolute quantification (iTRAQ) mass spectrometry (Ross et al, 2004). This identified secreted protein acidic and rich in cysteine (SPARC; or osteonectin) as a promising prognostic biomarker. Further investigation suggested that circulating levels of SPARC appear to originate from the stroma.

Materials and Methods

Patients and clinical materials. Three retrospective series of MPM patients were included in this study. The discovery series consisted of 12 patients from the parallel, non-randomized phase II studies investigating the effectiveness of thalidomide (arm A: thalidomide in combination with cisplatin and gemcitabine [n = 34]; and arm B: thalidomide alone [n = 29], recruited between April 2001 and August 2003) (Kao et al, 2012) consisting of the six shortest and six longest surviving patients (median overall survival [OS] 1.2 and 38.3 months, respectively; Supplementary Table 1 for patient characteristics). This sample set was used to identify circulating biomarkers associated with OS differences. Overall survival was defined as the time from enrolment to death, while progression-free survival (PFS) was defined as the time from enrolment to progression (or death if progression had not occurred). Collected blood was centrifuged at 2500 g for 10 min, and separated plasma was stored at −80 °C. Patients gave written informed consent under the protocol approved by the Human Research Ethics Committee (HREC) at Royal North Shore Hospital.

The second series consisted of 97 pathologically confirmed MPM patients treated at the Netherlands Cancer Institute between 1995 and 2011. Patients donated blood samples at the time of diagnosis, which were spun at 3100 r.p.m. for 10 min to isolate serum, which was then stored at −30 °C. This series was used for validation of candidate circulating protein biomarkers, which is the primary analysis in this study. Overall survival was defined as the time from diagnosis to death. Patients gave consent under the Institutional Biobank Programme approved by HREC at the Antoni van Leeuwenhoek Hospital-Netherlands Cancer Institute.

The third series consisted of archival tumour samples from 74 MPM patients treated with pemetrexed/cisplatin chemotherapy is associated with a limited prognostic role in MPM, with elevated levels of osteopontin and SMRP showing correlation with shorter survival (Grigoriu et al, 2007; Roe et al, 2008; Schneider et al, 2008). Although the concentration of fibulin-3 in the plasma did not correlate with survival, high levels in effusions were associated with shorter survival (Pass et al, 2012).

Identification of circulating blood-based biomarkers has also been attempted via proteomics-based approaches. Ostroff et al (2012) discovered and validated a panel of serum biomarkers as a non-invasive proteomics-based surveillance tool in the early diagnosis of MPM in patients at high risk for this disease. Using the Selected Reaction Monitoring (SRM) assay technology, Cerciello et al (2013) also identified serum protein-derived candidate biomarker panels for the diagnosis of MPM.

Given the feasibility of biomarker identification using proteomics-based technology and the lack of accurate prognostic biomarkers in MPM, we initially designed an exploratory proteomic study, in which we systematically investigated proteins present in plasma of MPM patients using the isobaric tag for relative and absolute quantification (iTRAQ) mass spectrometry (Ross et al, 2004). This identified secreted protein acidic and rich in cysteine (SPARC; or osteonectin) as a promising prognostic biomarker. Further investigation suggested that circulating levels of SPARC appear to originate from the stroma.

iTRAQ. Patient plasma samples from the first series were immunodepleted of the top 14 most abundant plasma proteins using a multiple affinity removal system (Agilent Technologies, Santa Clara, CA, USA) following the manufacturer’s direction. The unbound fraction was collected and precipitated in ice-cold acetone overnight. The sample was centrifuged at 14,000 g for 10 min to pellet the proteins. The aceton was decanted and pellet resuspended with 0.1 M triethylammonium bicarbonate before labelling for iTRAQ analysis. A common reference sample consisting of a pool of all samples was used in each iTRAQ experiment as the denominator for determining ratios. Samples were labelled by following the manufacturer’s protocol with modifications as previously described (Song et al, 2008). Tryptic peptides were fractionated by strong cation exchange chromatography then each fraction analyzed via information-dependent acquisition using reversed-phase nanoLC/MS using a TripleTOF 5600 mass spectrometer (ABSciex, Framingham, MA, USA). Data files were searched against the Human SWISS-PROT protein database using ProteinPilot (v4.0, ABSciex) with thorough search mode and bias correction. Proteins were assigned with a false discovery rate of <1%. Differential expression of proteins measured by iTRAQ between short- and long-MPM survivors was assessed using an empirical Bayes moderated t-test as implemented in the limma library from Bioconductor (Gentleman et al, 2004), as we have previously described (Jankova et al, 2011). A test P-value of ≤0.05 was regarded as evidence of differential abundance.

ELISA. The protein candidates were validated by quantification using commercially available ELISA kits in accordance with the manufacturers’ instruction, carried out by researchers blinded to the study endpoint. These included Selenoprotein P (qy-e01007; Qayee-Bio for Life Science, Shanghai, China), Tetranectin (E80350Hu; Uscn Life Science Inc, Wuhan, China) and SPARC (E90791Hu; Uscn Life Science Inc). Duplicate measures were made using commercially available ELISA kits in accordance with the manufacturers’ instructions, carried out by researchers blinded to the study endpoint. These included Selenoprotein P (qy-e01007; Qayee-Bio for Life Science, Shanghai, China), Tetranectin (E80350Hu; Uscn Life Science Inc, Wuhan, China) and SPARC (E90791Hu; Uscn Life Science Inc). Duplicate measures were made using commercially available ELISA kits in accordance with the manufacturers’ instructions, carried out by researchers blinded to the study endpoint. These included Selenoprotein P (qy-e01007; Qayee-Bio for Life Science, Shanghai, China), Tetranectin (E80350Hu; Uscn Life Science Inc, Wuhan, China) and SPARC (E90791Hu; Uscn Life Science Inc). Duplicate measures were made using commercially available ELISA kits in accordance with the manufacturers’ instructions, carried out by researchers blinded to the study endpoint. These included Selenoprotein P (qy-e01007; Qayee-Bio for Life Science, Shanghai, China), Tetranectin (E80350Hu; Uscn Life Science Inc, Wuhan, China) and SPARC (E90791Hu; Uscn Life Science Inc).
Tissue microarrays. Formalin-fixed paraffin-embedded tumour tissue blocks from the P/D procedure and normal mesothelium blocks from cardiac surgery were retrieved. Areas containing tumour and normal mesothelium, respectively, were marked on the haematoxylin and eosin slides; and the corresponding areas were determined on the FFPE blocks. Tissue microarrays (TMAs) were constructed as described previously (Kao et al, 2011). Briefly, a minimum of four 1-mm cores were sampled from the FFPE blocks and inserted into a recipient block, using the ATA-100 Advanced Tissue Arrayer (Chemicon, Temecula, CA, USA). Cores of smooth muscle were included as negative controls in each TMA (Supplementary Figure 1).

Immunohistochemistry. Serial 4-μm paraffin sections of the TMA blocks underwent immunohistochemical staining for SPARC. Sections were incubated with primary rabbit polyclonal anti-SPARC antibody (AB14174, dilution 1:1000; Abcam, Boston, MA, USA) for 32 min at room temperature after using CC2 (Ventana Medical Systems, Tucson, AZ, USA) as an antigen retrieval solution (citrate buffer pH 6) for 44 min at 97 °C. The reaction was developed with the UltraView DAB detection kit (Ventana Medical Systems), using BenchMark ULTRA (Ventana Medical Systems).

Immunostaining evaluation. Immunostaining was assessed by an expert pulmonary pathologist (WAC) who was blinded to the clinical data. Positive labelling was defined as cells with cytoplasmic staining of any intensity. The percentage of cells labelled by the antibodies (0–100%) was recorded in all assessable cores in a semi-quantitative manner. Separate scores were determined for both the tumour cells and the stromal fibroblasts. The final score for SPARC staining in samples from each patient was calculated from the average score of the available cores in the TMAs.

Cell lines: cell-conditioned medium and protein lysates. Five human mesothelioma cell lines (H28, H226, H2452 and MSTO) and the immortalized mesothelial cell line MeT-5A were obtained from the American Type Culture Collection (Manassas, VA, USA; it should be noted here that although listed as mesothelioma by ATCC, it has been debated whether the origin of the NCI-H226 cell line was a mesothelioma or a pleural metastasis from a squamous cell carcinoma of the lung). In addition, the previously described MPM lines MM05 (Relan et al, 2013), VMC23 (Kryeziu et al, 2013) and SPC111 (Schmitter et al, 1992) and the mesothelial line LP9 (Wu et al, 1982) were included. Cell lines were grown in their corresponding medium (RPMI-1640 for all MPM lines, DMEM for MeT-5A, M199 supplemented with 3.3 mM EGFr, 400 mM hydrocortisone and 1% insulin-transferrin-selenium for LP9) supplemented with 10% fetal bovine serum (FBS) at 37 °C, 5% CO2 and 95% humidity. All media and supplements were purchased from Life Technologies (Carlsbad, CA, USA) or Sigma-Aldrich (St Louis, MO, USA).

To obtain cell-conditioned medium, cells were grown to 80% confluence in T25 flasks in medium containing FBS, before medium was replaced with 2 ml serum-free medium. Cell-conditioned medium was collected after 24 h, cell debris removed by 5 min centrifugation at 1200 r.p.m., and supernatants stored at –80 °C. Protein lysates were prepared from the same cells by lysis in 300 μl RIPA buffer as described previously (Linton et al, 2014). Protein concentration was determined using the Pierce BCA Protein Assay Kit (Thermo Scientific, Waltham, MA, USA) according to the manufacturer’s instructions.

Mouse plasma and serum samples. Athymic (nu/nu) mice were purchased from the Animal Resources Centre (Perth, WA, Australia) and injected subcutaneously in the left flank with $5 \times 10^6$ H226 or $3 \times 10^6$ MSTO cells in 100 μl serum-free medium/ growth factor-reduced matrigel mix (1:1, matrigel from BD Biosciences, Franklin Lakes, NJ, USA). Once tumours reached around 300 mm3, mice were killed and blood was collected via cardiac puncture into either empty or EDTA-containing tubes. Serum samples were allowed to clot for 60 min at room temperature before being further processed as for plasma samples (centrifugation at 2500 r.p.m. for 20 min), and both were stored at –80 °C. Animal studies were approved by the SLHD Animal Welfare Committee.

Statistical analysis. The primary end point of the study was OS, with definitions stated above. The primary analysis was the validation of circulating SPARC in the Dutch series. Validation of ELISA protein quantification in plasma and serum was performed using the median protein level as a cutoff, to define the two groups of patients (protein-high vs protein-low). This was defined a priori.

The comparison of the baseline patient characteristics and survival in all patient cohorts was made using IBM SPSS Statistics, Version 19 (SPSS Inc, Chicago, IL, USA): chi-square test for categorical variables; Log-rank test for Kaplan–Meier survival analysis; and Mann–Whitney U-test for non-parametric distribution comparison. For the primary analysis of determination of prognostic value of circulating SPARC, multivariate analysis was performed using the Cox proportional hazards regression model incorporating age, gender, stage, histological subtype and circulating SPARC level (SPARC-high vs SPARC-low).

To determine the association of SPARC protein expression in the tumour samples with the clinical characteristics (such as age, gender and histological subtype), we used chi-squared test. Significant variables in the univariate analyses were entered into a logistic regression model without selection; and the results of the logistic regression modelling are presented as odds ratios (ORs) and associated 95% confidence interval (CIs). A P-value of ≤0.05 was considered as statistically significant.

RESULTS

Circulating SPARC has prognostic value in MPM. The 12 patients from series one were used for exploratory proteomic analyses. The total number of proteins identified was 226. The iTRAQ analysis of the samples from the short and long survivors revealed five plasma proteins that showed a statistically significant difference (P < 0.05) in abundance. Selenoprotein P and tetranectin were elevated in long-term survivors, while insulin-like growth factor-binding protein 2 (IBP2), platelet basic protein (CXC7) and SPARC were found to be reduced in plasma of long-term survivors (Supplementary Table 2). Further quantification by ELISA was performed for selenoprotein P, tetranectin and SPARC (Supplementary Table 3). Median protein levels were used to divide the 12 patients into protein-high vs protein-low for the individual proteins examined. Using the Kaplan–Meier method, SPARC was the only protein that differentiated the patient OS. Low level of SPARC was associated with long survival (median OS: 32.1 vs 1.2 months for low vs high SPARC; P = 0.006). Box plots are shown in Supplementary Figure 2 to demonstrate the differential abundance of SPARC.

To validate the association between SPARC and OS, SPARC levels were measured in samples from 97 patients from series two (patient characteristics are described in Table 1). At the time of the report, 92 patients were deceased. The median age of the patients was 60 years (range: 42–76 years), and the median OS was 13.5 months (95% confidence interval [CI]; 9.3–17.8 months). The median SPARC concentration measured by ELISA was 1.75 μg ml$^{-1}$ (range: 0.55–2.76 μg ml$^{-1}$; standard deviation [s.d.]) 0.41 μg ml$^{-1}$) in this series and was used to categorise patients into SPARC-high and SPARC-low groups. The median OS was significantly higher in patients with SPARC-low (19.0 months; 95% CI: 12.1–25.9 months) compared with SPARC-high patients (8.8 months; 95% CI: 7.8–9.9 months, P = 0.01; Figure 1A). The median OS was higher in female (14.7 months; 95% CI: 0–30.7) compared with male gender (10.7 months; 95% CI: 6.6–14.8
SPARC is overexpressed in MPM tumours. To determine the potential source of circulating SPARC, we first examined the SPARC protein expression in TMAs generated from archival MPM tumour samples from 74 patients who underwent P/D (series three). Owing to attrition of assessable cores, 72 patients were analysed for tumoral SPARC expression while 69 patients were assessed for stromal SPARC expression. We found both the SPARC IHC scores to be significantly higher in MPM tumour cells ($P = 0.001$) and MPM stromal fibroblasts ($P < 0.001$) compared with respective scores in the normal mesothelium (Figure 2C and D). The SPARC protein in the tumour cells tended to be universally expressed (median expression 100%; range 0–100%), while SPARC in the stromal fibroblasts was more heterogeneous (median expression 50%; range 0–100%). The box plots in Figure 2C and D demonstrate the distribution of the SPARC expression in these P/D patients.

Table 3 illustrates that stromal expression of SPARC protein was associated with non-epithelial subtype of MPM. Using logistic regression, high stromal SPARC expression (≥50%) remained independently associated with non-epithelial subtype (OR: 7.7; 95% CI: 2.3–26.2; $P = 0.001$). In contrast, SPARC protein tumoral expression was not associated with histological subtype ($P = 1.00$) but female patients were significantly more likely to have SPARC expression in the tumour cells ($P = 0.02$; Table 2). In addition, low stromal SPARC (≤50%) was associated with longer survival (10.9 months vs 7.6 months; $P = 0.001$; Figure 2E) while there was no association between tumoral SPARC and patient survival ($P = 0.71$). In contrast, in a multivariate Cox proportional hazard regression model ($n = 69$) incorporating stromal SPARC, age, gender and histological subtype, histological subtype remained an independent predictor of prognosis (HR: 2.47; 95% CI: 1.38–4.44; $P = 0.002$), while stromal SPARC did not (HR: 1.42; 95% CI: 0.76–2.63; $P = 0.27$). This is likely to be a result of the strong association between histological subtype and stromal SPARC expression.

SPARC in mesothelioma

**Figure 1. Kaplan–Meier curves for the patients in series two according to serum SPARC (A) and gender (B).**
Circulating SPARC is likely secreted from the stroma of MPM tumours. To investigate whether tumour or stromal cells are the source of circulating SPARC, we evaluated cellular and secreted SPARC levels in vitro. We found that cellular SPARC expression was higher in 5 out of 7 cell lines than in the two immortalised mesothelial lines (Figure 3). An association between histological subtype and cellular SPARC was not evident. Assessment of SPARC levels in cell-conditioned medium revealed a lack of secreted SPARC in all cell lines (Figure 3). This finding was mirrored by the observation that human SPARC was not detectable in the plasma or serum of MPM xenograft-bearing mice (Figure 3). In contrast, in a parallel study using the same samples, we were able to detect another secreted protein, Fibulin-3, in the cell-conditioned medium of all cell lines and in the plasma of xenograft-bearing mice (Kirschner et al., 2015). The lack of secretion of SPARC by MPM cell lines suggests stromal cells within the tumour, rather than the tumour cells themselves, are the source of circulating SPARC.

### Table 3. Association of SPARC protein expression and patient characteristics in the P/D patients (series three)

| Factors          | Groups | Stomal SPARC-high (>50%) | Presence of tumoral SPARC (100%) |
|------------------|--------|--------------------------|----------------------------------|
|                  |        | Yes | No | % Yes | P-value | Yes | No | % Yes | P-value |
| Age (years)      | <60    | 5   | 14 | 26     | 0.03    | 18  | 3  | 86    | 0.24    |
|                  | ≥60    | 28  | 22 | 56     | 0.38    | 36  | 15 | 71    | 0.02    |
| Gender           | Male   | 28  | 27 | 51     | 0.03    | 40  | 18 | 69    | 0.24    |

**Abbreviations:** P/D, pleurectomy ± decortication; SPARC, secreted protein acidic and rich in cysteine.

Figure 2. Immunohistochemical staining for SPARC. (A) Sarcomatoid histological subtype with high SPARC expression in tumour cells (arrows) and stroma (arrowheads). (B) Epithelioid mesothelioma with high SPARC expression in tumour (arrows) and low SPARC expression in stromal cells (arrowheads). (C) Epithelioid mesothelioma with low SPARC expression in tumour (arrows) and low SPARC expression in stromal cells (arrowheads). SPARC immunohistochemistry scores for mesothelioma compared with normal pleural mesothelium are shown in (D) tumour cells and (E) stromal fibroblasts. Kaplan–Meier curve for patients undergoing P/D according to stromal SPARC is shown in (F).
with item 17 of the REMARK guidelines (McShane et al., 2005). Prognostic factors (age, histological subtype and stage), consistent with commonly accepted standard significance of circulating SPARC in the Dutch series (our primary endpoint). An important aspect of our study is that it adheres to the REMARK guidelines where applicable, and uses pre-specified methods and analyses. Although our initial exploratory study demonstrated the feasibility of using iTRAQ proteomic techniques to investigate potential prognostic protein biomarkers in plasma of MPM patients. With this methodology, we have shown that it is possible to identify candidate plasma proteins with potential clinical significance, even in a relatively rare disease such as MPM. We used iTRAQ initially as a profiling tool to determine whether there were differentially expressed proteins between the two groups of 12 patients divided by their survival. We observed a good separation between the samples from long and short survivors when restricting our analysis to the five proteins identified as differentially expressed: SPARC, selenoprotein P, tetranectin, IBP2 and CXCL7. We then proceeded to quantify the selected protein levels by ELISA, which is often considered as the gold standard in protein quantification. We found that high plasma levels of SPARC remained associated with short survival. This finding was consistent in the iTRAQ and ELISA experiments involving the 12 plasma samples of MPM patients, thus making this protein the most promising candidate biomarker in our exploratory study. To confirm this hypothesis-generating finding from our Australian patient cohort, we assessed serum SPARC concentrations using ELISA in an independent cohort of MPM patients from the Netherlands. We confirmed the prognostic value of circulating SPARC, adjusting for known prognostic factors such as age, gender, stage and histological subtypes. While promising, our study is limited by its retrospective nature and the non-randomised allocation of treatment groups. Nevertheless, SPARC emerged as the most robust prognostic biomarker, given that the direction of prognostication was consistent between iTRAQ and ELISA in the discovery series as well as the validation series. Further independent validation, preferably in a prospective study, is needed to confirm the prognostic value of circulating SPARC in MPM patients. A particular strength of our study is that it adheres to the REMARK guidelines where applicable, and uses pre-specified methods and analyses. Although a retrospective study, the characteristics of the study patients, the treatments received and the type of biological materials used and method of preservation and storage are clearly described. Most importantly, the multivariate model examining the independent significance of circulating SPARC in the Dutch series (our primary analysis) was fit to variables significant in the univariate analysis (SPARC and gender) as well as commonly accepted standard prognostic factors (age, histological subtype and stage), consistent with item 17 of the REMARK guidelines (McShane et al., 2005).
finding is consistent with a previous study, which showed that although both pancreatic cancer-derived fibroblasts and pancreatic cancer cell lines expressed SPARC, only the fibroblasts secreted SPARC in large quantities (Saito et al, 2003). One explanation for this observation could be related to the recent finding that the intracellular acidification frequently observed in cancer cells was able to reduce the secretion of SPARC and other extracellular matrix proteins by melanoma cells (Bellenghi et al, 2015). As human SPARC was not detectable in the serum or plasma of MPM xenograft-bearing mice, it further argues for a stromal origin for the SPARC detected in patient serum. Nevertheless, although our in vitro and in vivo experiments suggest that circulating SPARC is secreted from the stromal fibroblasts rather than the tumour cells, other cell types could be the source of SPARC, such as tumour-associated macrophages (Sangaletti et al, 2008). Further studies are required to definitively identify the origin of SPARC in patient serum.

In our current study, we did not examine the mechanism of SPARC upregulation in MPM compared with normal mesothelium. In glioma, miR-145 is downregulated, leading to increased expression of connective tissue growth factor (CTGF), which in turn leads to upregulation of SPARC (Lee et al, 2013). In MPM, it has been reported that CTGF is upregulated in rat sarcomatoid MPM (Jiang et al, 2014), and miR-145 is lower in MPM tumours and cell lines compared with normal tissues (Ciocca et al, 2014). Therefore, we hypothesised that decreased miR-145 in MPM could in turn lead to increased CTGF and upregulated SPARC. Examination of the functional role of SPARC in MPM was also beyond the scope of the current study. However, in gastric cancer where in line with our findings, there is a high SPARC expression in tumour and its expression is associated with poor prognosis, preclinical work has demonstrated that downregulation of SPARC inhibits invasion and growth of human gastric cancer cells (Yin et al, 2010). This is the subject of further study in our group. Prognostication in MPM is important given the heterogeneity of the tumour biology. If accurate prognostic stratification indicates a short time to death, then either palliative therapy or best supportive care alone may be appropriate; while a more aggressive approach to therapy may be offered if long survival is indicated. In addition to being a prognostic biomarker, SPARC may also be a potential predictive biomarker for chemotherapy sensitivity. There is an emerging association between tumoral and stromal SPARC and pancreatic adenocarcinoma (Neuzillet et al, 2013). Secreted protein acidic and rich in cysteine is overexpressed in the stroma of pancreatic cancer and has been investigated as a target for nab-paclitaxel. Nab-paclitaxel is a solvent-free, albumin-bound form of paclitaxel, which is an anti-microtubule agent used to treat a number of cancers. It has been shown that SPARC acts as a high-affinity receptor for albumin, resulting in increased intratumoral uptake of the drug. In a phase I/Ii study evaluating gemcitabine plus nab-paclitaxel in pancreatic adenocarcinoma, stromal SPARC expression was associated with improved OS, indicating that it may be a useful predictive biomarker for response to nab-paclitaxel-based regimen (Von Hoff et al, 2011). In a retrospective review of the SPARC expression in patients from the CONKO-001 study (randomised phase III study investigating the role of adjuvant gemcitabine vs observation in resected pancreatic cancer), authors found that the negative prognostic impact was only restricted to patients who received adjuvant gemcitabine. This would suggest that SPARC is a predictive marker for response to gemcitabine, which is a chemotherapeutic agent commonly used in MPM (Sinn et al, 2014). Therefore, we believe that further clinical studies examining the predictive value of stromal SPARC expression in MPM patients undergoing gemcitabine or nab-paclitaxel would be worthwhile.

In conclusion, we have demonstrated that it is feasible to use well-validated proteomic methods to explore potential biomarkers in the plasma of MPM patients and showed SPARC to be a promising circulating prognostic biomarker. Furthermore, we validated the independent prognostic importance of circulating SPARC in a large retrospective series of MPM patients. While promising, this finding should be confirmed in a prospective manner before it could potentially be used clinically. We also demonstrated the presence of SPARC protein in the MPM tumour cells as well as the stromal fibroblasts, with our results, indicating the stroma as the likely source of the circulating SPARC. We believe that our findings indicate the potential biological importance of SPARC in MPM and further studies examining the function of SPARC in MPM are warranted.

ACKNOWLEDGEMENTS

This work was funded by the Cancer Institute New South Wales (CINSW) Innovation Grant (to SC and NVZ) and the Workers’ Compensation Dust Diseases Board (DBB) of New South Wales Research Grant Scheme (to GR, SC, MM, SC and NVZ). Part of this work was undertaken at APAF, with the infrastructure provided by the Australian Government through the National Collaborative Research Infrastructure Strategy (NCRIS). Support from the National Foundation for Medical Research and Innovation is also gratefully acknowledged for part of this study.
