ABSTRACT
We have observed four low-luminosity active galactic nuclei (AGNs) classified as type 1 Low-Ionization Nuclear Emission-Line Regions (LINERs) with the X-Ray Telescope (XRT) and the Ultraviolet–Optical Telescope (UVOT) onboard Swift, in an attempt to clarify the main powering mechanism of this class of nearby sources. Among our targets, we detect X-ray variability in NGC 3998 for the first time. The light curves of this object reveal variations of up to 30 per cent amplitude in half a day, with no significant spectral variability on this timescale. We also observe a decrease of ~30 per cent over 9 d, with significant spectral softening. Moreover, the X-ray flux is ~40 per cent lower than observed in previous years. Variability is detected in M81 as well, at levels comparable to those reported previously: a flux increase in the hard X-rays (1–10 keV) of 30 per cent in ~3 h and variations by up to a factor of 2 within a few years. This X-ray behaviour is similar to that of higher luminosity, Seyfert-type objects. Using previous high-angular-resolution imaging data from the Hubble Space Telescope (HST), we evaluate the diffuse UV emission due to the host galaxy and isolate the nuclear flux in our UVOT observations. All sources are detected in the UV band, at levels similar to those of the previous observations with HST. The XRT (0.2–10 keV) spectra are well described by single power laws and the UV-to-X-ray flux ratios are again consistent with those of Seyferts and radio-loud AGNs of higher luminosity. The similarity in X-ray variability and broad-band energy distributions suggests the presence of similar accretion and radiation processes in low- and high-luminosity AGNs.

Key words: galaxies: active – galaxies: nuclei – ultraviolet: galaxies – X-rays: galaxies.

1 INTRODUCTION
Low-luminosity active galactic nuclei (AGNs) are a common phenomenon, with a large fraction of all massive galaxies displaying some weak activity that is likely of non-stellar origin (see e.g. Ho 2008, and references therein). Understanding the demographics and physics of these objects is a necessary step towards the comprehension of supermassive black hole activity in the local Universe and its past evolution. Low-Ionization Nuclear Emission-Line Regions (LINERs), in particular, are a class of low-luminosity AGNs defined on the basis of their optical spectral line ratios (Heckman 1980; Ho 2008) and can be further divided into various sub-classes according to their different properties (Chiaberge, Capetti & Macchetto 2005; Gonzalez-Martin et al. 2009). A fundamental question about these sources is the origin of their optical spectrum and multiwavelength emission in general: it is not clear which fraction of the powering source is non-stellar and, if it is due to accretion, what is the regime of the accretion and the efficiency of the radiation conversion. It has been argued that the lack of X-ray variability (e.g. Komossa, Böhringer & Huchra 1999; Roberts, Warwick & Ohashi 1999; Georganopoulos et al. 2002; Pellegrini et al. 2003; Ho 2008), the non-detection of broad Fe Kα lines down to stringent limits (Ptak et al. 2004) and the weakness or absence of the characteristic ‘big blue bump’ in their optical/near-ultraviolet (UV) spectra, traditionally observed in Seyferts (Quataert et al. 1999; Chiaberge et al. 2006), indicate that their engines may be intrinsically different from those of the more luminous AGNs, and could consist of radiatively inefficient accretion flows (RIAFs).

*Hydrogen column densities derived from Kalberla et al. (2005) and consistent with the A_b extinction values reported in (Maoz 2007), using a typical Milky Way gas-to-dust ratio, 5 × 10^{-21} \text{ cm}^{-2} \text{ mag}^{-1}.

*Hydrogen column densities from the XRT spectral fits.

*Photon index, f_\nu \propto E^{-\Gamma}.

*Unabsorbed flux in units of 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}.

*Unabsorbed monochromatic luminosity at 2500 Å, in units of 10^{25} \text{ erg s}^{-1} \text{ Hz}^{-1}.

1Eddington ratio based on the observed SEDs.

However, X-ray observations of most of these sources have been sparse and not sensitive or not long enough to detect significant variability, except in M81, one of the closest and best studied bona fide (e.g. Kewley et al. 2006) LINERs. Furthermore, UV monitoring with the Hubble Space Telescope (HST) Advanced Camera for Surveys (ACS) of a sample of 17 LINERs has revealed the presence of bright and variable UV nuclei (Maoz et al. 2005). By coupling these UV measurements with non-simultaneous X-ray measurements with ASCA, Chandra and XMM–Newton, Maoz (2007) has shown that the UV-to-X-ray flux ratios in LINERs are similar to those of much–more–luminous Seyferts. Thus, contrary to the common paradigm, rather than being qualitatively different from Seyferts, LINERs may instead be ‘scaled–down’ analogues of Seyferts, with similar emission mechanisms operating in both classes.

While the arguments of Maoz (2007) are supported by accurate photometry, the UV and X-ray data of his sample were not simultaneous, with measurements often separated by years. LINERs exhibit variability, which, albeit not of very large amplitude (by factors of up to a few in the UV on time–scales of years; Maoz et al. 2005), may undermine the results derived from non–simultaneous observations.

In this paper, we approach this problem by obtaining, for the first time, simultaneous X-ray and UV data, along with X-ray variability information, for a small sample of LINERs. The NASA satellite Swift is well suited to this task because it is a flexible and efficient facility for long simultaneous and accurate UV and X-ray monitoring. Results of this work have been presented in preliminary form in Romano et al. (2009).

Throughout this paper the uncertainties are given at 90 per cent confidence levels for one interesting parameter (i.e. Δχ^2 = 2.71), unless otherwise stated. The spectral indices are parametrized as \nu \propto v^{-\Gamma}, where \nu is the frequency as a function of energy \nu; we also use \Gamma = \alpha + 1 as the photon index, N(E) \propto E^{-\Gamma} (\text{photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}). This paper is organized as follows. In Section 2 we describe our sample, observations, analysis and results obtained with the two Swift instruments; in Section 3 we construct the spectral energy distributions (SED) and in Section 4 we discuss our findings.

2 SAMPLE, OBSERVATIONS, DATA ANALYSIS AND RESULTS

Our sample consists of the brightest LINERs in the Maoz (2007) UV sample, but excluding M87, because of its prominent jet, which would dominate the UV emission at the Swift resolution. The sample includes M81, NGC 3998, NGC 4203 and NGC 4579 (see Table 1), which are all type 1 LINERs (i.e. with detected broad H\alpha components) according to the classification by Ho et al. (1997). These four objects form a rather homogeneous sample (see Maoz 2007): all have similar UV and X-ray luminosities (10^{40} to 10^{41} \text{ erg s}^{-1}), radio loudness parameters (~100), optical–to–X-ray indices \alpha_{opt}~1, central black hole masses (10^7 to 10^8 M\odot), three of which are measured directly from stellar or gas kinematics) and Eddington ratios (~4.5 to ~5.5).

The Swift archive\footnote{http://swift.gsfc.nasa.gov/docs/swift/archive/} already contained data for two of these sources, M81 and NGC 4203, which had been observed as Swift fill–in targets, and which we retrieved. M81 was observed for 33.7 ks and has an X-Ray Telescope (XRT; Burrows et al. 2005) spectrum of excellent quality. NGC 4203 had a good XRT spectrum, although somewhat underexposed compared to M81 (5.3 ks). We observed NGC 3998 and NGC 4579 with Swift for the first time as Targets of Opportunity (ToO) for 27.4 and 20.8 ks, respectively.

2.1 XRT

Table 2 reports the log of the Swift/XRT observations used for this work. The XRT data were processed with standard procedures (XRTPIPELINE v0.11.6), filtering and screening criteria by using FTOOLS in the HEASOFT package (v6.4). Given the low count rate of the sources during the respective observing campaigns (<0.5 counts s^{-1}), we only considered photon counting data (PC), and further selected XRT grades 0–12. No pile–up correction was required. The source events were extracted in circular regions centred on the source, with radii depending on the source intensity (10–20 pixels, 1 pixel ~2.37 arcsec), while background events were extracted in source–free annular or circular regions, depending on the field.

Spectra were extracted for each XRT observation, as well as for the cumulative observing campaigns. Ancillary response files were generated with XRTMKARF, and account for different extraction regions, vignetting and point spread function (PSF) corrections. We used the v010 spectral redistribution matrices available in the calibration data base maintained by HEASARC. All spectra were rebinned with a minimum of 20 counts per energy bin to allow \chi^2 fitting within XSPEC (v11.3.2).

We extracted XRT light curves from the same regions as for the spectra for source and background in the standard bands, 0.2–10 keV (total), 0.2–1 keV (soft, S) and 1–10 keV (hard, H). For our
analysis, we considered several time bins ranging from 120 s to the typical orbit duration ($\lesssim 5800$ s), and the minimum time bin was chosen to ensure that each light-curve point would have at least 30 source-plus-background counts. The exposure requirements were that the bins be at least 50 per cent exposed. In each case, the light curves were corrected for PSF losses, i.e. losses due to the extraction region geometry, and bad/hot pixels and columns falling within this region.

The host galaxy contribution in the XRT extraction region was evaluated using archival *Chandra* images of these LINERs obtained with the longest exposures with ACIS-S. We evaluated the counts in the following regions: (i) R1, an annulus with outer radius equal to the XRT extraction radius for each object and inner radius 4 arcsec, i.e. the radius including 99 per cent of the *Chandra* PSF; (ii) R2, a circular region of 4-arcsec radius; (iii) R3, an annular region of radii 4 and 4.5 arcsec. We assumed that R1 only contained host galaxy photons, R2 only active nucleus photons, while R3 was used to evaluate the galaxy counts in R2 assuming a constant host galaxy intensity profile. The measured counts in R3 were scaled to the area of R2 and added to the counts in R1, thus obtaining an estimate of the host galaxy counts in the whole XRT extraction region. The host galaxy contribution to the X-ray emission of the four LINERS ranges from 6 (NGC 3998) to 16 per cent (NGC 4203), and was therefore subsequently ignored.

M81 and NGC 3998 display a few very rapid (minute time-scale) flux changes of 30 to 60 per cent. Although this exceeds the typical level of XRT photometric stability, which is about 10 per cent (as established on the basis of the flux stability of the standard source PSR 0540–69; Cusumano, private communication), we note that these occur at low flux levels, so that we cannot assess their authenticity. Therefore, we have considered only fluxes integrated over time-scales no shorter than one orbit for further variability analysis.

Since the *Swift* satellite must resettle on the target at every orbit, the target’s location within the XRT field of view may change from orbit to orbit, and occasionally the source flux is greatly underestimated because of the vicinity of a detector dead column that affects the PSF to various degrees. We have systematically checked our observations for this effect and have corrected for it (see Grupe et al. 2007). However, because of the low flux level of our sources, in many cases the PSF reconstruction is not fully satisfactory and the corresponding flux points have been excluded from our variability analysis.

The orbit-averaged light curves of M81 and NGC 3998 indicate variability. In Figs 1(c), (d) and 2(b) we show the flux and hardness ratio time series of M81 and NGC 3998 during the pointings when significant variations were observed. The M81 hard X-ray light curves in 2006 June (Fig. 1c, middle panel) and November (Fig. 1d, middle panel) have $\chi^2 \approx 30$ [for 5 degrees of freedom (d.o.f.)] and $\chi^2 \approx 41$ (19 d.o.f.) with respect to the average flux, respectively, corresponding to probabilities of constancy of $10^{-3}$ or less. The variations in hard X-rays have a maximum amplitude of 30 per cent in a time-scale of 3 to 12 h. The variability in soft X-rays is less pronounced, but well correlated with the hard X-rays, so that the hardness ratio is not significantly variable on these time-scales.

*Note that the durations of our XRT observations are similar to the monitoring times adopted by those authors, making the comparison of the $\sigma_{\text{rms}}^2$ parameters meaningful.*

---

$^\text{a}$We only considered data collected in PC observing mode.
Figure 1. Swift/XRT background-subtracted light curves (count rate in counts s\(^{-1}\)) and hardness ratios (i.e. 1–10 to 0.2–1 keV flux ratios) of M81. The binning time interval corresponds to the orbit duration. Panels (a) to (e) report the 0.2–1 keV (top), 1–10 keV (middle) light curves and hardness ratio curves (bottom) of each pointing (see Table 2). Start times (\(t = 0\)) correspond to (a) 2005 April 21.033 UT, (b) 2005 August 25.056 UT, (c) 2006 June 24.004 UT, (d) 2006 November 18.045 UT, (e) 2007 February 6.906 UT. Panel (f) reports the 0.2–1 keV (filled circles) and 1–10 keV (open circles) light curves of M81 between 2005 and 2007. Each point is the average of the flux measured during each pointing in that given band and each curve is normalized to its average (0.16 and 0.29 counts s\(^{-1}\) for the 0.2–1 and 1–10 keV curves, respectively). The time origin (\(t = 0\)) corresponds to 2005 April 21.0 UT.

June almost achromatically and then increases by 2007 February by a factor of 2 in the soft X-rays and slightly less in hard X-rays. The variability on year time-scales is well correlated in the two bands, with no significant variations of the hardness ratio. The 1–10 keV flux of NGC 3998 decreases by 30 per cent in the 9 d separating our two observations, while the 0.2–1 keV flux decreases more slowly, implying a softening of the spectrum. Indeed, the hardness ratio (i.e. the 1–10 to 0.2–1 keV flux ratio) decreases significantly between
Low-luminosity AGNs with Swift

Figure 2. Swift/XRT background-subtracted light curves (count rate in counts s\(^{-1}\)) and hardness ratios (i.e. 1–10 to 0.2–1 keV flux ratios) of NGC 3998. The binning time interval corresponds to the orbit duration. Panels (a) and (b) report the 0.2–1 keV (top), 1–10 keV (middle) light curves and hardness ratio curves (bottom) of each pointing (see Table 2). Start times \((t = 0)\) correspond to (a) 2007 April 20.628 UT, (b) 2007 April 29.11 UT. Panel (c) reports the 0.2–1 keV (filled circles) and 1–10 keV (open circles) light curves of NGC 3998 in 2007. Each point is the average of the flux measured during each pointing in that given band and each curve is normalized to its average (0.11 and 0.22 counts s\(^{-1}\) for the 0.2–1 and 1–10 keV curves, respectively). The time origin \((t = 0)\) corresponds to 2007 April 20.0 UT.

Although the uncertainties on the fitted hydrogen column densities (Table 1, column 4) are not small, all sources – except NGC 4203, whose spectrum has a poor signal-to-noise ratio – show significant evidence for absorption in excess of the Galactic one (also reported in Table 1).

2.2 UVOT

The Swift Ultraviolet– Optical Telescope (UVOT; Roming et al. 2005) observed the four targets with the filters \(u\) (3465 Å), \(uvw1\) (2600 Å), \(uvm2\) (2246 Å), \(uvw2\) (1928 Å) simultaneously with the XRT. The filter choice was driven by the objective of maximizing the nuclear signal, which is dominant in the UV, while minimizing the stellar emission from the bulge populations of the target galaxies. For each object, after verifying that the UVOT counts show no significant variability, we have co-added the images.

The data analysis was performed using the \textsc{uvotsource} task included in the latest \textsc{heasoft} software. This task normally calculates the magnitude by means of aperture photometry within a circular

by guest
on 28 July 2018
region of 5-arcsec radius, which includes more than 99 per cent of the signal of a point source, and applies specific corrections due to the detector characteristics. Since the adoption of this standard aperture often resulted in oversubtraction of the host-galaxy background, we used instead an aperture of 2-arcsec radius, and applied the proper correction factor between a 2 and a 5 arcsec radius aperture (see below). Because of its proximity (3.6 Mpc), the host galaxy of M81 occupies most of the field-of-view of UVOT, making it difficult to estimate the sky background to be subtracted from the nucleus and the galaxy light. The background was therefore computed from a 20.7 arcsec radius circular region separated by 6.5 arcmin from the nucleus. For uniformity, the remaining three LINERs, albeit more distant, were treated in the same way.

Using archival HST images of these LINERs at 2500 and 3300 Å obtained with the High Resolution Channel (HRC) of the HST ACS (Maoz et al. 2005), we have evaluated the nuclear point source subtracted host galaxy contribution for each object in a 2 arcsec radius circular area centred on the nucleus, and have interpolated or extrapolated the UV host galaxy fluxes to the central wavelengths of the UVOT u band and UV filters, in order to subtract them from the observed fluxes.

While the aperture-summed galaxy light is clearly detected in the HST images, the surface brightness is too low and the images are too oversampled to determine the surface brightness profiles of the galaxies on the scales of the apertures we use here. Different galaxy profiles will require different corrections for PSF losses outside the aperture. For the galaxy light subtraction, we have therefore considered two extreme cases: one in which the galaxy light is highly centrally concentrated, and one in which it has constant surface brightness. In the former scenario, the adoption of a 2-arcsec radius for the UVOT photometry results in a galaxy light loss similar to that suffered by the nuclear light, and therefore we first corrected the observed 2 arcsec radius flux to a 5 arcsec radius aperture, and then subtracted the galaxy flux evaluated from the HST images. In the latter case, where the light profile is flat, the galaxy light suffers no net PSF losses in the UVOT photometry, and we therefore first subtracted the HST galaxy flux from the total observed UVOT flux and then applied the 5 arcsec radius aperture correction to the remainder, which represents the point-source nuclear flux.

The host galaxy contribution is dominant in the u band (it is generally comparable to the total flux observed by UVOT) and decreases with decreasing wavelength to the uvv2 filter (1928 Å) where it contributes, at most, 50 per cent of the observed flux. The first galaxy-subtraction method described above predictably results in systematically larger nuclear fluxes than obtained with the second method. As also expected, the differences between the results of the two methods decrease as one goes to shorter wavelengths, where the galaxy light becomes less dominant.

All UVOT magnitudes have been converted into fluxes using the latest in-flight flux calibration factors and zero-points (Poole et al. 2008). The average observed fluxes with their statistical errors are reported in Table 3, where we also list the host galaxy fluxes measured in the HST images and converted to the wavelengths of the UVOT filters, and the final nuclear fluxes obtained with the two subtraction methods described above.

3 SED CONSTRUCTION

We combined the XRT spectra, corrected for the total hydrogen absorption (Table 1, column 4), and the UVOT fluxes, corrected for their host galaxy backgrounds and dereddened using the $A_B$ extinction values compiled by Maoz (2007) from Schlegel, Finkbeiner & Davis (1998), and adopting the Galactic extinction curve of Cardelli, Clayton & Mathis (1989). These UV-to-X-ray spectral energy distributions (SED) are shown in Fig. 6. The errors associated with the UVOT nuclear fluxes are the sum in quadrature of the uncertainties associated with the observed UVOT fluxes (including the statistical errors reported in Table 3 and the systematic errors given in Poole et al. 2008) and the uncertainties of the galaxy HST measurements (Table 3), increased by 5 per cent – summed in quadrature – to take into account the uncertainty in the background subtraction on the
Low-luminosity AGNs with Swift

Figure 5. Swift/XRT spectra of the sample. The stepped curves represent the single absorbed power laws which best fit the spectra (see Table 1 for spectral parameters).

Table 3. Swift/UVOT observations.

\(a\) Not corrected for Galactic reddening, in \(10^{-15} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Å}^{-1}\).
\(b\) Total flux, evaluated in a 2 arcsec radius circular area centred on the nucleus, and scaled to the equivalent flux in a 5 arcsec radius area using the UVOT PSF. The errors are statistical only (1\(\sigma\)).
\(c\) Extranuclear galaxy flux within a 2 arcsec radius circular area centred on the nucleus, obtained by interpolating/extrapolating from archival HST ACS HRC images at 2500 and 3300 Å. The errors are statistical only (1\(\sigma\)).
\(d\) Net nuclear flux, obtained by assuming that the host galaxy radial profile is highly centrally concentrated.
\(e\) Net nuclear flux, obtained by assuming that the host galaxy radial profile is nearly flat, i.e. constant within the UVOT 2 arcsec radius aperture.
\(f\) The errors are propagated from the Swift UVOT and HST ACS HRC uncertainties and include the systematic uncertainties.

For comparison, we have plotted also the previously measured UV-to-X-ray measurements (see fig. 1 in Maoz 2007) and the mean SEDs of radio-loud and radio-quiet quasars from Elvis et al. (1994), normalized to go through the geometric mean of the two nuclear...
4 DISCUSSION

We have observed four bright LINERs with XRT and UVOT onboard Swift, to study their variability and their simultaneous UV-to-X-ray ratios, in an attempt to probe their emission mechanisms. In particular, high-luminosity AGNs – Seyferts and quasi-stellar objects (QSOs) – are generally thought to be powered by geometrically thin and optically thick accretion discs. Our new data can bring new insight to the question of whether low-luminosity AGNs – specifically LINERs – are simply lower power analogues of Seyferts and QSOs, or are instead powered by some fundamentally distinct process, such as a RIAF.

Among our results is the first detection of X-ray variability in NGC 3998, in a range of time-scales from a few hours to days, with a ∼30 per cent amplitude. This is in contrast to earlier reports of no X-ray variability during BeppoSAX and XMM–Newton observations (Pellegrini et al. 2000b; Ptak et al. 2004). The reason for this difference may be related to the larger sensitivity of XRT with respect to BeppoSAX, and to XRT’s higher scheduling flexibility, which allows for longer monitoring periods than possible with XMM–Newton. Pellegrini et al. (2000b) have cited the absence of variability in NGC 3998 as evidence that the accretion is advection dominated in this source. Other workers (Ptak et al. 1998; Ho 2008) have, in general, invoked non-variability in X-rays as an indicator of a RIAF mode. Our finding of significant short-term X-ray flux variations in a low-luminosity LINER points, instead, to a similarity with whatever accretion mode is occurring in higher luminosity AGNs.

However, the excess variance parameter of the NGC 3998 XRT light curves does not obey the inverse relation between X-ray luminosity and variability amplitude determined for high-luminosity AGNs (Nandra et al. 1997; Turner et al. 1999) when this is extrapolated to the X-ray luminosity of NGC 3998 (1.1 × 10^40 erg s^{-1} in 2–10 keV). Instead, the variability amplitude is similar to that typical of Seyferts of luminosity 10^{43}–10^{44} erg s^{-1} (2–10 keV). The range of validity of the relation may thus not extend to the low X-ray luminosities of the objects studied here.

A second LINER in our sample, M81, has already been shown to be X-ray variable on many time-scales, from hours to years (Pellegrini et al. 2000a; Iyomoto & Makishima 2001; La Parola et al. 2004; Page et al. 2004; Young et al. 2007; Markoff et al. 2008). Our findings confirm this behaviour and set this object, together with the other LINERs in our sample, as interesting objects to study in detail.

fluxes at 1928 Å obtained with the two galaxy subtraction methods described above. Note that the fluxes in this band suffer the least galaxy contamination, and therefore represent a solid lower limit to the intensity of the UV component.
along with NGC 3998, as another X-ray-variable low-luminosity AGN that is similar in this respect to high-luminosity AGNs. It has been suggested that the mechanisms active in this object are similar to those that cause the hard states in X-ray binaries (Markoff et al. 2008). Our observation of spectral softening accompanying source brightening on a time-scale of years is indeed reminiscent of the behaviour exhibited, on a shorter time-scale, by Galactic sources.

Our XRT timing results on NGC 4203 and NGC 4579 are inconclusive. NGC 4203 exhibits no significant X-ray variability on any time-scale, despite being, among the sources in Maoz (2007), the one that varied with the largest amplitude in the UV. One reason may be that our monitoring period was limited, and hence we did not catch the stochastically occurring variations. Alternatively, for this object the errors associated with orbit-averaged points are somewhat larger than those of M81 and NGC 3998, so that interorbit variations of amplitude similar to the interorbit variations in M81 and NGC 3998 would not be detected at high significance. A prominent, variable Fe Kα emission line has been detected by ASCA and \textit{XMM–Newton} in NGC 4579, and has given rise to various interpretations as to its origin from a standard accretion disc or a truncated disc (Terashima et al. 1998, 2000, 2002; Dewangan et al. 2004). Our weak XRT detection of the feature does not add significantly to this debate.

Our sources are all well detected in at least one UV filter (Fig. 6). The UV-to-X-ray SEDs compare rather well with those reported by Maoz (2007) and obtained with non-simultaneous UV and X-ray data. The X-ray spectrum of the LINERs always lies about a factor of 3 to 10 above the normalized radio-loud quasar template, depending on the object and on the wavelength. The UV flux level has not changed dramatically in any of the sources (Fig. 6), although these are among the most UV-variable sources in the Maoz (2007) sample. We note, however, that the UVOT fluxes are more uncertain than the \textit{HST} measurements, owing to the galaxy subtraction and to the lower angular resolution and photometric accuracy of UVOT. The XRT fluxes and spectra are also similar to the older ones, except for NGC 3998, which XRT has detected in a state lower by \~{}40 per cent than observed in 1999 and 2001 by \textit{BeppoSAX} and \textit{XMM–Newton}, respectively (Ptak et al. 2004; see also Fig. 6b).

We have evaluated the Eddington ratios of our LINERs using the bolometric luminosities and the central black hole mass estimates compiled in Maoz (2007). The bolometric luminosities were obtained from the normalized templates of radio-loud AGNs (Elvis et al. 1994) from 3465 Å to 0.2 keV and the observed X-ray spectrum from 0.2 to 10 keV. In fact, the template may be a more reliable description of the spectrum at UV wavelengths (considering that some of our UV points are upper limits), while at X-rays the template always underestimates the real flux (see Fig. 6). In the radio-loud AGN spectrum, the UV-to-X-ray flux dominates the SED, representing more than half of the total emission. Moreover, considering that the intrinsic AGN spectra probably lack the conspicuous observed bump centred at 1 μm, due to reprocessed radiation at shorter wavelengths (Marconi et al. 2004), our computed bolometric luminosities may adequately represent the intrinsic luminosities after all. The Eddington ratios, reported in Table 1, are about 0.5 dex higher than those computed by Maoz (2007), who only included the UV luminosity, but are still low, as typical for LINERs.

By normalizing the AGN templates to the UV emission, we note that the precisely determined XRT spectral slopes follow the average radio-loud AGN shape, although, as noted, the spectral normalizations exceed the prediction by 0.5 to 1 order of magnitude (Fig. 6).

Strateva et al. (2005) and Steffen et al. (2006, hereafter S06) have studied the dependence of the optical-to-X-ray colour index, \( \alpha_{\text{ox}} \), of AGNs (defined – using our notation for the spectral indices, see last paragraph of Section 1 – as \( \alpha_{\text{ox}} = \frac{-0.3838 \log(l_{\text{1keV}}/l_{2500 \AA})}{\log(l_{\text{1keV}}/l_{2500 \AA})} \), where \( l_{\text{1keV}} \) and \( l_{2500 \AA} \) are the rest-frame X-ray and UV monochromatic luminosities in erg s\(^{-1}\) Hz\(^{-1}\), respectively) on the monochromatic rest-frame UV luminosity, and have found an empirical linear relation between those quantities (the parameters of the relation in the two works coincide, within the errors; we have used that of S06, which is based on a larger sample). We have extrapolated \( \alpha_{\text{ox}} \) in the S06 relation, \( \alpha_{\text{ox}} = 0.137 \log(l_{2500 \AA}) - 2.638 \) (note that we have changed the sign of their equation 2, to be coherent with our spectral index notation), by two orders of magnitude to low UV luminosities, corresponding to the observed monochromatic UV luminosities of the LINERs in our sample (extinction corrected, see Table 1, column 9). This extrapolation is plotted as a short-dashed line in Fig. 6. It can be compared to a power law passing through our observed luminosities at 2500 Å and 2 keV, shown in Fig. 6 as a solid line, with errors omitted, for clarity.

In NGC 3998 and NGC 4579 the observed values of \( \alpha_{\text{ox}} \) coincide, to within the errors, with the extrapolation to low luminosities of the S06 relation. In M81 and NGC 4203, the less UV-luminous sources in our sample (see Table 1), \( \alpha_{\text{ox}} \), has an intermediate value, similar to those of Seyferts, and the extrapolated \( \alpha_{\text{ox}} \) is significantly flatter than the observed one and predicts X-ray luminosities that are four–five times higher than observed. As already noted by S06 based on their data alone, and further pointed out by Maoz (2007) based on his non-simultaneous UV and X-ray measurements, the S06 relation probably flattens at luminosities below \~{}10\(^26\) erg s\(^{-1}\) Hz\(^{-1}\). Overall, our present simultaneous UV and X-ray photometry strengthens the case for a limiting value of \( \alpha_{\text{ox}} \) below some critical luminosity typical of Seyferts.

In summary, for the LINERs under study, the significant UV emission, the X-ray intraday variability and the X-ray and multiwavelength spectral similarity with radio-loud AGNs all point to continuity and similarity with AGNs of higher luminosity. In view of this, it is not clear that distinct accretion and radiation mechanisms are required in the different luminosity regimes. Further \textit{Swift}/XRT and UVOT monitoring, or more optimally, new \textit{HST} high angular resolution UV observations of larger samples, accompanied with XRT simultaneous coverage, could shed more light on these questions.

We note, finally, that we cannot exclude that, in these sources, the emission at X-ray and/or UV bands is partially due to a weak jet, some evidence of which has been reported for all of our four sources, either directly (for M81, based on resolved radio structure detection and radio polarization) or indirectly (for NGC 3998, NGC 4203, NGC 4579, based on a flat radio spectrum, a compact and variable radio core, and high brightness temperature) from high-resolution radio imaging (Bietenholz, Bartel & Rupen 2000, 2004; Bower, Falcke & Mellon 2002; Filho, Barthel & Ho 2002; Anderson, Ulvestad & Ho 2004; Ros & Perez Torres 2008). In the case of NGC 3998, a jet has been proposed by Ptak et al. (2004) as possibly responsible for the multiwavelength emission. Jetted high-energy radiation in this LINER would be compatible both with the rapid flux variations and with the frequency-dependent variability amplitude that we observe over 9 d (Fig. 2c), which is typical of non-thermal sources (e.g. Ulrich-H., Maraschi & Urry 1997), and which is dissimilar to the X-ray variability observed in Seyferts (usually of larger amplitude at softer energies e.g. Matsuoka et al. 1990; Nandra, Pounds & Stewart 1990; Edelson et al. 2000; Turner et al. 2001; Uttley & McHardy 2005; Terashima et al. 2009) and in weak-line radio galaxies (e.g. Gliozzi et al. 2008). However, it would be
to draw a conclusion on the exact nature of the X-ray emitting process from the detection of spectral softening accompanying flux decrease between only two epochs in this individual LINER. More work on the correlated radio and X-ray variability in LINERs – in both the observational and the theoretical directions – is necessary to assess the role of a jet in the multiwavelength emission (see e.g. Brenneman et al. 2009).

ACKNOWLEDGMENTS

We thank N. Gehrels for approving this set of ToOs and the Swift team, in particular the duty scientists and science planners, for making these observations possible. We are grateful to S. Immler and T. Belloni for kindly sharing their data on M81 and NGC 4203, G. Casusmano, D. Grupe, S. Holland and J. Nousek for advice on the Swift instruments and to C. Guidorzi for helpful discussion. We want to thank the anonymous referee for constructive comments that helped improving our presentation. PR thanks INAF–IASFMI, and DM thanks INAF – Osservatorio Astrofisico di Arcetri, where parts of this work were carried out, for their kind hospitality. This work was supported by grants ASI-INAF I/023/05/0 and ASI I/088/06/0. DM thanks the DFG for support via German–Israel Project Cooperation grant STE1869/1-1.GE625/15-1. This research has made use of NASA’s Astrophysics Data System Bibliographic Services, as well as the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

Facilities: Chandra, Swift, Hubble Space Telescope.
