A Novel Human Erythrocyte Glycosylphosphatidylinositol (GPI-anchored) Glycoprotein ACA

ISOLATION, PURIFICATION, PRIMARY STRUCTURE DETERMINATION, AND MOLECULAR PARAMETERS OF ITS LIPID STRUCTURE

A method has been elaborated to isolate and purify up to homogeneity a novel membrane glycoprotein containing a glycosyl-phosphatidylinositol (GPI) anchor by means of salting out with ammonium sulfate (40–80% saturation), followed by preparative SDS-PAGE, chromatography and acetone precipitation. The preparation obtained was homogeneous upon electrophoresis in the presence of 0.1% SDS after reduction with 2-mercaptoethanol. It is protein-soluble at its isoelectric point (pI 5.5) with molecular mass of 65,000 daltons. The isolated protein is linked to the membrane via glycosylphosphatidylinositol susceptible to cleavage by purified phospholipase C. The hydrophobic portion of the glycolipid membrane anchor of the protein was radiolabeled with the photoactivated reagent 3-(trifluoromethyl)-3-(m-[125I]iodophenyl) diazirine and hydrolyzed with glycosylphosphatidylinositol-specific phospholipase C, followed by enzymatic deacetylation of the remaining lipid. Thin-layer chromatography showed that the generated radiolabeled fragment migrates with the same mobility as that of variant surface glycoprotein (VSG), obtained in the same manner. In this study we describe a novel erythrocyte membrane GPI-linked protein with the structural feature of an anchor that, in contrast to other GPI-linked erythrocyte proteins, has a non-acetylated inositol ring and diacylglycerol rather than alkylacyl glycerol as a lipid tail of the anchor.

Many proteins of eukaryotic cells are anchored to the membrane by covalent linkage to glycosyl-phosphatidylinositol (GPI)1. Those proteins lack a transmembrane domain, have no cytoplasmic tail, and are therefore located exclusively on the extracellular side of the plasma membrane. Glycosylated phosphoinositol-anchored molecules are a structurally diverse family of biomolecules (1–3) that includes: protozoan coat components, activation antigens, complement regulatory proteins, adhesion molecules, membrane-associated enzymes, and many others glycoproteins. This type of cell membrane attachment implies that the protein moieties of these antigens are located outside the membrane, have potentially high lateral mobility, and may be released from the cell by the action of GPI-specific phospholipase C. GPI anchors may be considered as a reasonably well defined class of the structures because important elements are conserved over a wide range of phylogeny, from protozoan parasites to mammals. This anchor contains a linear core glycan sequence of ethanolamine-PO4-6-Manα1-2-Manα1-6Manα1-4GlcNH2-α1-6myo-inositol-1PO4-lipid. The heterogeneity among different GPI-anchored proteins occurs mainly in the lipid composition. The variant surface glycoprotein (VSG) anchors contain only dimyristoyl phosphatidylinositol (4), whereas GIs of Leishmania promastigote surface proteinase and many mammalian GPI-anchored proteins including those on the erythrocyte such as acetylatedinositine (AcE), decay-accelerating factor (DAF), and membrane inhibitor of reactive lysis (MIRL) (5), contain almost exclusively 1-alkyl-2-acylphospholipid, which appear to be characteristic of human anchors in general (6). In addition, some GPI anchors contain an additional fatty acid (palmitate) in a hydroxyster linkage to the inositol ring, which renders them resistant to the action of bacterial phosphatidylinositol-specific phospholipase C (PI-PLC) and the GPI-specific phospholipase C (GPI-PLC) from Trypanosoma brucei. The basis of this phospholipase resistance was first described for human erythrocyte acetylatedinositine (7), and subsequently for human erythrocyte decay-accelerating factor (5). The presence of a substitution on the 2-position of the inositol ring would explain the PI-PLC resistance of the palmitoylated anchors since the bacterial PLC enzyme operates via nucleophilic attack of the phosphorus atom by the hydroxyl group at the 2-position of the inositol ring. This finding led to the suggestion that occupation of the myo-inositol 2-position hydroxy group by palmitate would automatically preclude the action of this enzyme (8). As shown for DAF and some other GPI-linked proteins they can exhibit differential inositol acetylation, and this structural variation is regulated in a cell-specific fashion, but can also be protein-dependent (9). The biological relevance of GPI anchor structural variability among different blood cell types remains incompletely understood. The presence of additional fatty acid chain (acylation) in the hydrophobic domain probably improves the attachment of the molecule to the external leaflet of the mem-

This paper is available on line at http://www.jbc.org
brane. The presence of this acyl-chain on the inositol ring in erythrocyte-associated anchors renders these structures resistant to cleavage by PI-PLC and less sensitive to PI-PLD cleavage when purified. The resistance to be released by phospholipases, either by blocking the lytic mechanism of a phosphatidyl-specific phospholipase C or by retaining membrane association following cleavage of phosphatidylic acid by anchor-specific phospholipase D, may enhance the membrane stability of these proteins over time, consistent with the longer (120 day) life span in the circulation of erythrocytes as compared with leukocytes. We report here on a novel GPI-linked erythrocyte membrane protein with an anchor sensitive to phospholipases C and unusual structure of the lipid portion of protein, distinct from that of other erythrocyte (DAF, LFA, MIRL, and acetylcholinesterase) proteins.

EXPERIMENTAL PROCEDURES

Purification and Isolation of Protein—Human blood withdrawn from healthy donor was centrifuged at 1500 × g at 4 °C for 10 min. Plasma and buffy coat were removed by aspiration, and packed cells were washed twice in 150 mM/15 mM sodium phosphate (pH 7.6) and lysed in CH3COOH/distilled water. Membranes were pelleted at 10,000 × g for 15 min and washed with extraction buffer, 50 mM Tris-HCl, pH 7.5, 2 mM dithiothreitol, 1 mM phenylmethylsulfonyl fluoride, 1 mM EDTA, 0.25 M sucrose. This step was repeated until the ghosts showed no visual evidence of residual hemoglobin. (Three washes were usually required). After the last wash, the ghosts were resuspended in the same buffer. The pellet was frozen in liquid nitrogen for 15 min and thawed at 25 °C. This procedure was repeated three times. The homogenate was then adjusted to 400 mM with respect to KCl and centrifuged at 25,000 × g for 60 min. The supernatant was collected and adjusted to 70% saturation with (NH4)2SO4 (Sigma) and stirred for 30 min. The precipitated proteins were collected by centrifugation, redissolved in the extraction buffer, and precipitated again with 40% saturation with (NH4)2SO4 (see Fig. 2A). The precipitated proteins were stirred again for 30 min on ice, redissolved in extraction buffer, and dialyzed against storage buffer (40 mM Tris-HCl, pH 7.5, 2 mM dithiothreitol, 1 mM EDTA, 0.25 M sucrose), and stored at −20 °C. The pure amphiphilic form of protein was obtained by further preparative steps including SDS-gel electrophoresis. The gel bands of the protein were excised and form of protein was obtained by further preparative steps including 70% saturation with (NH4)2SO4 (Sigma) and stirred for 30 min. The treated with trypsin or Asp-N at 37 °C for 4.5 h in a freezer, neutralized, and recovered in 0.5% ammonium bicarbonate. N-terminal sequences were determined by automated Edman degradation using gus phase sequencer. Subsequently, a search in the human sequence database was performed (www.ncbi.nlm.nih.gov/entrez/query.Fcgidb = protein).

Cell-free Extracts—Preparation of ghosts was done according to protocol approved by the Institutional Review Board of the New York Blood Center. Briefly, about 2.3 × 1011/ml packed red cells and erythrolyke mia cells (K-562) were washed once with phosphate-buffered saline buffer at 5000 rpm for 5 min. After the supernatant was decanted, the cells were lysed with 1:20:5 dilution of phosphate-buffered saline in distilled water and centrifuged at 15,000 rpm for 10 min. Supernatant was decanted, and the discrete pellet of the white cells adhering to the centrifuge tube was removed, too (12). Resuspended ghosts were washed with 10 mM Tris-HCl (pH 7.8) until they became white and anchor-saturated volume of simple buffer was added and boiled for 1 min before subjected to SDS-PAGE using 4.5 stacking gel and 4–15% separating gel.

Immunoblotting—Membrane proteins (10–30 μg) prepared from the erythrocyte ghosts and homogenized tissue of erythrolykemia (K-652) cells were mixed with reducing sample buffer and subjected to SDS-PAGE and then transferred to nitrocellulose membrane. The filters were blocked with 3% bovine serum albumin in phosphate-buffered saline and used for testing antibody reactivity. Polyclonal mouse serum against a 65-kDa GPI-protein was used at a dilution of 1:5000. Visualization was performed using anti-IgG secondary antibody and conjugated with alkaline phosphatase and 5-bromo-4-chloro-3-indolyl phosphatase (Promega). Thin-layer Chromatography (TLC)—Samples of GPI-PLC (Bacillus cereus, Roche Molecular Biochemicals) were performed in triethanolamine buffer (50 mM triethanolamine, 10 mM EDTA, and 10 mM sodium azide, pH 7.5) for 1 h at 37 °C. Digestion with purified phospholipase D (from bovine serum EC 3.1.4.50 Roche Molecular Biochemicals) was performed in 20 mM Tris-HCl, pH 7.4, 0.1 mM CaCl2, Triton X-100 0.008% (w/vol.) for 60 min at 37 °C. After the reactions were finished, 10 μl of reducing sample buffer was added. Tubes containing the reaction mixtures were placed in a boiling water bath for 5 min, and aliquots of the samples were subsequently subjected to analysis by SDS-PAGE and silver staining (PhastSystem from Amersham Biosciences).

Anti-Cross-reacting Determinant (CRD) Assay—The GPI-PLC-, PI-PLC-, and GPI-PLD-cleaved proteins were subjected to SDS-PAGE and transferred onto nitrocellulose. After blocking, the antigens were visualized with affinity-purified anti-CRD antibody (GlycoScience, Oxford). After washing, bound anti-CRD antibody was detected by biotinylated donkey anti-rabbit IgG and visualized with streptavidin horseradish peroxidase. As positive and negative controls, the soluble form of variant surface glycoprotein and the membrane form of ACA were blotted simultaneously and revealed with anti-CRD antibody.

Identification of Products of Phospholipases Action—Purified ACA protein was digested with PI- and GPI-phospholipases C and subjected to further hydrolysis with triacylglycerol acyl hydrolase (300 units) (Rhizopus arhizus EC 3.1.1.1, Roche Molecular Biochemicals) followed by carboxylic ether hydrolase (30 units) (from pig liver EC 3.1.1.11, Roche Molecular Biochemicals) in reaction buffer containing 0.1 mg of SDFS/m for 25 min at 37 °C. Glycerol is described as described by phospholipase A1 (Roche Molecular Biochemicals) with glycerol kinase (GK) pyruvate kinase (PK), and lactate dehydrogenase (LDH) as auxiliary and inducible enzymes (Roche Molecular Biochemicals). Lipase, esterase, PK, LDH, and GK were free from hexokinase, as well as other interfering kinases and phosphatases; ATP (Roche Molecular Biochemicals) was substantially free from ADP and P-enolpyruvate (Roche Molecular Biochemicals). The decrease in the extinction at 340, 334, and 365 nm due to oxidation of NADH was measured (Fig. 1).

Radiolabeling—Purified proteins were labeled with 3-(trifluoromethyl)-3-(3′-[(125)I]iodophenyl)diazirine (125TI) (Amersham Bio- sciences) by photolysis at 350 nm for 15 min as described by Roberts and Rosenberry (13). A 0.1-mu of aliquot of (125TI)ITD in ethanol (5–200 μl) was mixed with 0.25–1 ng of purified protein in a 1 cm2 rubber-stoppered borosilicate glass test tube and agitated gently to ensure complete mixing. Photolysis was performed for 20 min in a Beckman spectrophotometer with the slits removed.

Novel Human Membrane Glycoprotein
PLC cleaved [\(^{125}\text{I}\)]-TID-labeled proteins were subjected to further hydrolysis with triacyl glycerol-protein acylhydrolase followed by carboxylic-ester hydrolase, and the lipid products of this reaction were extracted with chloroform/methanol/HCl (22:50:1) and centrifuged for 15 min at 300 H11003 g. The lower phase was removed and evaporated to dryness under nitrogen. The residues were resolved in 0.1 ml of chloroform/methanol (2:1), and these solutions were quantitatively applied to TLC plates. Thin-layer chromatography was performed on 10 H11003 20-cm Silica Gel plates (Merck, Darmstadt, Germany) without activation. Development was either with solvent B (hexane/diethylether/acetonic acid (60:30:1)) or solvent A (hexane/2-propanol, (96:4)). The positions of radioactive components were identified by autoradiography with Kodak XAR-5 film. The positions of standards were located by exposure of dried plates to iodine vapor.

**RESULTS**

**Purification of ACA**—A two-step purification procedure was applied for the preparation of the protein. The first step includes the disruption of the hemoglobin-free membrane followed by repeated precipitation with ammonium sulfate of various saturation grades and preparative electrophoresis (Fig. 2A). The purity of preparations was evaluated by SDS-PAGE (Fig. 2, A and B) and IEF, (Fig. 3, A and B). Preparations were obtained from various batches of pooled human erythrocytes. No degradation products were identified in any preparation.

**Amino Acid Sequencing of Purified ACA**—Purified and chemically deglycosylated ACA was subjected to N-terminal amino acid sequencing. No sequence was obtained, indicating a blocked N terminus. Therefore, the protein was inactivated and trypsinized, and sequence was established for 11 internal peptides (Fig. 4). Only peptide A shows homology with the 1230–1246 region of the \(^{9251}\text{H9251}\)-chain of human erythrocyte spectrin (14).

**Digestion with Phospholipases**—We further focused our attention on the biochemical characterization of this protein, particularly of its lipid portion, and compared it with some other GPI-linked molecules expressed on the surface of human erythrocytes.

The susceptibility of a protein to release from a membrane surface by bacterial PI-PLC is the original indicator for the

As shown in Fig. 5, there was no portion of the ACA protein that remained resistant to anchor-degrading phospholipases. As negative control, the native form of ACA and GPI-PLD-cleaved protein were blotted simultaneously and labeled with anti-CRD antibody. The GPI-PLD-cleaved molecules do not react with anti-CRD antibodies indicating that this enzyme leaves phosphodiacylglycerol and 1,6-d-myo-inositol as reaction products, destroying the CRD antigenic determinant by preventing the formation of d-myo-inositol 1,2-cyclic phosphate. The membrane form of ACA was also used as a negative control; as expected, it was not recognized by anti-CRD antibodies.

Identification of the Lipid Substituents of the ACA Anchor—PI- and GPI-PLC-digested purified protein was further hydrolyzed with triacylglycerol acyl-hydrolyze, giving the 1,2-diacylglycerol, alkylacylglycerol and the phosphorylated polar head group, while the phospholipases D hydrolyzes the phosphodiester linkage to produce a phosphorylated 1,2-diacylglycerol, alkylacylglycerol and the polar head group with an exposed hydroxyl group. The phospholipases D hydrolyzes the phosphodiester linkage to produce 1,2-diacylglycerol, alkylacylglycerol and the phosphorylated polar head group.

The ACA protein treated with glycosyl-phosphatidylinositol phospholipase D shows no changes in electrophoretic mobility when compared with the native protein (Fig. 5B). The lower electrophoretic mobility of GPI-PLD-digested protein, when compared with the PI-PLC digested one, is due to the lack of a phosphate (negative charge) on the inositol ring of the degraded protein.

Presence of the CRD Epitope on ACA—A polyclonal antibody raised to soluble VSG cross-reacts with other unrelated GPI-anchored proteins. This CRD is only exposed when the protein is converted into a hydrophilic form by the action of either bacterial PI-PLC or eukaryotic GPI-PLC. In the case of the soluble form of variant surface glycoprotein, three overlapping epitopes are involved in this recognition: the inositol 1,2-cyclic phosphate generated on phospholipase C cleavage of the anchor, the non-acetylated glucosamine residue, and the variable galactose branch. It is also known that regarding mammalian proteins the major epitope involved in this recognition is the inositol 1,2-cyclic phosphate (16). Thus, the recognition of a protein following phospholipase C cleavage by an anti-CRD antibody is the most powerful evidence for the presence of a GPI anchor. In the next set of experiments we sought to determine whether anti-CRD antibodies recognized a soluble form of isolated ACA protein. As demonstrate here, human erythrocyte GPI anchor. In the next set of experiments we sought to determine whether anti-CRD antibodies recognized a soluble form of isolated ACA protein. As demonstrate here, human erythrocytes ACA exhibit >99% PI-PLC sensitivity to the action of phospholipases C. Glycosyl-phosphatidylinositol phospholipase C-digested protein was electrophoresed and then subjected to Western blotting using anti-CRD antibody (Fig. 6). As positive control, the membrane form of variant surface glycoprotein (mVSG) was digested with the same anchor-degrading phospholipases. As negative control, the native form of ACA and GPI-PLD-cleaved protein were blotted simultaneously and labeled with anti-CRD antibody. The GPI-PLD-cleaved molecules do not react with anti-CRD antibodies indicating that this enzyme leaves phosphodiacylglycerol and 1,6-d-myo-inositol as reaction products, destroying the CRD antigenic determinant by preventing the formation of d-myo-inositol 1,2-cyclic phosphate. The membrane form of ACA was also used as a negative control; as expected, it was not recognized by anti-CRD antibodies.

Identification of the Lipid Substituents of the ACA Anchor—PI- and GPI-PLC-digested purified protein was further hydrolyzed with triacylglycerol acyl-hydrolyze, giving the 1,2-diacylglycerol, alkylacylglycerol and fatty acid as first reaction products followed by carboxylic ester hydrolase, an enzyme that accelerates the total hydrolysis of the lipid tail of the ACA anchor and enzymatic reactions for determinations of glycerol are outlined in Fig. 1. The decrease in extinction at 340, 334, and 365 nm due to oxidation of NADH is measured, and released glycerol calculated in g/liter. The amounts of released glycerol by hydrolysis with PI and GPI-phosphatidylinositol-specific phospholipases followed by specific deacetylation were similar, indicating the same specific activity of both enzymes on ACA (Table I). To further investigate the structure of the hydrophobic domain in red blood cells ACA, particularly the fatty acids composition, we analyzed the fragments gener-
TABLE I

| Release of glycerol    | 0.045 g/liter | 0.038 g/liter |

Table showing the amount of released glycerol after total hydrolysis of ACA lipid tail.

We tested the photo-activated reagent \(^{[\text{125I}]}\text{TID}\), which was shown to partition strongly in favor of the lipid phase of membranes. Samples of \(^{[\text{125I}]}\text{TID}\)-labeled, purified proteins were subjected to hydrolysis with GPI-terpaphospholipase C. The lipid products of these reactions were further hydrolyzed with highly specific lipases. Radiolabeled fragments were extracted and analyzed by thin layer chromatography and autoradiography. The membrane form of variant surface glycoprotein from \(T.\ brucei\) was \(^{[\text{125I}]}\text{TID}\)-labeled and hydrolyzed in the same manner as ACA and subjected to thin-layer chromatography as a control (Fig. 7).

The major lipid species obtained by total hydrolysis of anchor of ACA exhibited the same mobility as labeled fatty acid tail of commercially available VSG, indicating the same 1,2-diacyl myristate structure. This structure differs from other erythrocyte GPI-linked proteins, which have alkyl-acyl glycerol and different fatty acids as a lipid tail of a molecule.

Generation of an ACA-specific Antibody and Detection of Its Expression on Erythrocytes—We established a purification method to obtain large amounts of protein necessary for immunization of 6 BALB/c mice according to standard procedures. To improve our understanding of this novel molecule, we first produced a mouse polyclonal antibody and tested its specificity with different samples of crude protein extract, purified protein, red cell membrane, and cell-free extracts. The specificity of the polyclonal antibody was tested in Western blots with various protein fractions. Ammonium sulfate protein extract obtained from erythrocyte membranes as described under “Experimental Procedures” was dissolved in storage buffer diapered against the same buffer and subjected to reducing SDS-PAGE. The homogeneously purified ACA protein and protein extracts obtained from erythrocyte ghosts and ghosts obtained from human erythroleukemia cell line (K-562) were subjected to SDS-PAGE and then transferred to nitrocellulose membranes. The polyclonal mouse serum specifically reacted with the 65-kDa band corresponding to ACA protein (Fig. 8). No reaction with other proteins was observed. The faint band of antibody to this novel antigen and a very low abundance of this molecule in the plasma membrane of red blood cells compared with human blood malignant cells.

DISCUSSION
We describe here the isolation and purification up to homogeneity of a novel human erythrocyte membrane protein called ACA. The protein was identified first, on SDS-PAGE as a faint band of ~65 kDa in a protein fraction obtained from erythrocyte ghosts. After the protein extract was treated with PI-PLC the faint band disappeared, indicating the existence of an anchor on this protein. For purification of this protein of unknown function, a classical protein chemical method was established. For further characterization of this protein, we provide two lines of evidence. The first line of evidence indicates the homogeneous protein preparation with an isoelectrical point at pH 5.5 and molecular mass of 65,000 Daltons. Mouse polyclonal antiserum raised against the purified protein specifically recognizes a protein with the same molecular mass in various protein and cell-free extracts. The second line of evidence indicates that erythrocyte ACA anchor structure differs from that of other GPI-linked erythrocyte membrane proteins. The ability of bacterial PI-PLC to release proteins attached to the membrane has permitted the identification of several phos-phatidylinositol-anchored proteins (18). PI-PLC and GPI-PLC treatment of ACA extracted from red blood cells results in a...
shift in the electrophoretical gel indicating a phosphinositool structure on this protein. As judged from the gel, the whole amount of the protein was hydrolyzed, indicating that the anchor of the protein exists on the surface of the erythrocyte membrane exclusively in a non-acetylated form, which means that the myo-inositol 2-position hydroxy group is not additionally acetylated in ACA molecule. Additional evidence supporting this lipid structure of ACA was provided by immunoblotting with anti-CRD antibody including appropriate controls. In immunoblot analysis, purified anti-CRD antibody recognizes the phospholipase-solubilized form of ACA. The protein was recognized by anti-CRD antibody after PI-PLC digestion because this antibody reacts to a large extent with the inositol 1,2-cyclic phosphate epitope generated after PI-PLC cleavage. The treatment with GPI-PLD, however, results in the complete loss of this epitope due to inositol-1,2-cyclic-phosphate removal. Phospholipase D degraded a lipid anchor other than phospholipase C by leaving phospholipid as final reaction product. Furthermore, the anti-CRD antibody also failed to recognize the membrane form of ACA protein, indicating the specificity of the reaction. Specific hydrolysis of the lipid tail of the anchor proteins provides evidence for the diacyl nature of glycerol binding. The first enzyme, triacylglycerol-acylhydrolase from Rhizopus arrhiizus, belongs to that group of esterases that hydrolyze sub-

shift in the electrophoretical gel indicating a phosphinositool structure on this protein. As judged from the gel, the whole amount of the protein was hydrolyzed, indicating that the anchor of the protein exists on the surface of the erythrocyte membrane exclusively in a non-acetylated form, which means that the myo-inositol 2-position hydroxy group is not additionally acetylated in ACA molecule. Additional evidence supporting this lipid structure of ACA was provided by immunoblotting with anti-CRD antibody including appropriate controls. In immunoblot analysis, purified anti-CRD antibody recognizes the phospholipase-solubilized form of ACA. The protein was recognized by anti-CRD antibody after PI-PLC digestion because this antibody reacts to a large extent with the inositol 1,2-cyclic phosphate epitope generated after PI-PLC cleavage. The treatment with GPI-PLD, however, results in the complete loss of this epitope due to inositol-1,2-cyclic-phosphate removal. Phospholipase D degraded a lipid anchor other than phospholipase C by leaving phospholipid as final reaction product. Furthermore, the anti-CRD antibody also failed to recognize the membrane form of ACA protein, indicating the specificity of the reaction. Specific hydrolysis of the lipid tail of the anchor proteins provides evidence for the diacyl nature of glycerol binding. The first enzyme, triacylglycerol-acylhydrolase from Rhizopus arrhiizus, belongs to that group of esterases that hydrolyze substrates quantitatively to glycerol and fatty acids, especially the \( \alpha \) and \( \beta \)-esters of glycerol and long chain fatty acids. Carboxylic ester hydrolysis, with its high specificity to monoglycerides, was facilitating the total hydrolysis of the anchor. Glycerol was a final product of these reactions, and its amount was determined according to standard procedure (17). The amounts of glycerol released from ACA by enzymatic deacylation with bacterial and eukaryotic phospholipases was similar in both cases, but bacterial PI-phospholipase C seemed to be more active than eukaryotic GPI-phospholipase. In this paper, we documented that \( ^{125} \)I-TID specifically labels the hydrophobic domain of ACA. After total lipid hydrolysis, extraction of fatty acids, and analysis on silica thin-layer chromatography exclusively myristic acid was found. All these data provide a strong evidence that ACA protein has an anchor based on diacylmyristate, a structure very similar to that of mVSG of \( T. \) brucei. Previous characterizations of different GPI-anchored proteins on the surface of erythrocytes such as DAF, CD59, LFA-3, and AchE, have shown that these proteins exhibit differential inositol acylation, a structural variation regulated in a cell-specific fashion (5). It seems that the precursor pools for both PLC-sensitive and PLC-resistant anchors exist in a number of cells and that the proportion of attached glycolipid anchors arising from these two pools is both tissue and protein specific (7, 9). It has recently been shown (9) that inositol acylation in mature surface proteins is regulated via posttransfer deacylation, occurring in endoplasmic reticulum immediately after GPI transfer, which in general is cell-specific but also can be protein-dependent. The structural feature of phospholipids of all these erythrocyte GPI-anchored proteins is based on 1-alkyl,2-acyl-glycerol in contrast to unacylated dimyristoylphosphatidylinositol, which is uniformly present in trypanosome membrane from variable surface glycoproteins. This first comparison of GPI anchors from different proteins expressed in the same tissue suggests that human reticulocytes produce only one type of anchor structure (19), and furthermore also GPI-anchored proteins from other cell types seem to have exclusively alkylacylglycerol as a lipid backbone (20). The experiments described in this study provide evidence that ACAs GPI anchor phospholipid head group differs from that of known erythrocytes GPI-linked proteins like DAF, acetylcholinesterase, and MIRL. The anchor we describe here consists principally of the minimum core glycan sequence Man\(_{n+2}\)-Man\(_{n+2}\)-GlcN-linked to a phosphatidylinositol with the structure sn-1-O-acetyl-2-O-acetylglycerol-3-phospho-myosin. This structure is essentially identical to dimyristoylphosphatidylinositol, which is uniformly present in \( T. \) brucei mVSG, the first protein in which GPI anchors were chemically characterized (21). Western blot analysis of whole protein extracts, purified ACA, and ghosts prepared from red blood cells and cells from erythrocytomegaly (K-562) with polyclonal anti-mouse antibody confirm the specificity of antibody. Moreover the same analysis indicates a very low abundance of this molecule in the membrane of red blood cells and apparently much higher expression in malignant cells.

Sequence analysis of 11 peptides obtained from ACA by trypsin digestion showed no homology with protein sequences of the data bank except for peptide A (Fig. 4), which exhibited partial identity with the 1230–1246 region of human erythrocyte spectrin. Search in the human sequence data bank was not successful; therefore, we concluded that the ACA sequence is not contained in the Human Genome data base.

We report here for the first time the existence of a novel erythrocyte GPI-phospholipase C-sensitive GPI-linked protein with the diacyl structure of the lipid backbone. The functional relevance of this molecule should be further elucidated. In fact, very little is known about the functional significance of these variations in the fatty acid linkage and composition of glycosylphosphatidylinositol among various cell types. They are certainly not relevant for their anchoring function but may profoundly influence their sensitivity to endogenous phospholipases C or D as well as the biological activity of the glycerolipid derivatives resulting from these hydrolysis reactions. The inositol glycan, diacylglycerol, and phosphatidic acid internally generated are well known intermediates in membrane signaling events and activate the cascade of intracellular second messengers (22). Diacylglycerol and phosphatidic acid are all mitogenic (23). Diacylglycerol is involved in protein kinase C activation (24), and phosphatidic acid can induce growth factor-like effects (25), including expression of tyrosine kinases and stimulation of DNA synthesis. The objective of our future work will be to investigate the significance of this unusual PI structure and its consequences for the function of ACA.
