Abstract

Photoelectron spectroscopy is a powerful tool for studying photoionization in atoms, molecules and solids [1–6]. With the advent of new light sources, photoelectron spectroscopy using intense, short pulses has become available, revealing important information about electron dynamics and time-dependent phenomena [7–10]. In particular, it allows for characterizing the light-matter interaction of increasingly complex systems [1, 3, 5]. Photoelectron spectra (PES) and photoelectron angular distributions (PAD) contain not only fingerprints of the interaction of the electrons with the electromagnetic fields, but also of their interaction and their correlations with each other [11]. PAD in particular can be used to uncover electron interactions and correlations [12, 13].

Tailoring the pulsed electric field in its amplitude, phase or polarization allows to control the electron dynamics, with corresponding signatures in the photoelectron spectrum [14–18]. While it is natural to ask how the electron dynamics is reflected in the experimental observables—PES and PAD [14–18], it may also be interesting to see whether one can control or manipulate directly these observables by tailoring the excitation pulse. Moreover, one may be interested in certain features such as directed electron emission without analyzing all the details of the time evolution. This is particularly true for complex systems where it may not be easy to trace the full dynamics all the way to the spectrum. The question that we ask here is how to find an external field that steers the dynamics such that the resulting photoelectron distribution fulfills certain prescribed properties. Importantly, the final state of the dynamics does not need to be known. The desired features may be reflected in the angle-integrated PES, the energy-integrated PAD, or both.

To answer this question, we employ optimal control theory (OCT), using Krotov’s monotonically convergent method [19] and adapting it to the specific task of realizing photoelectron distributions with prescribed features. The photoelectron distributions are calculated within the time-dependent configuration interaction singles scheme (TDCIS) [20], employing the splitting method for extracting the spectral components from the outgoing wavepacket [21, 22]. While OCT has been utilized to study the quantum control of electron dynamics before, in the framework of TDCIS [23] as well as the multi-configurational time-dependent Hartree-Fock (MCTDHF) method [24] or time-dependent density functional theory (TDDFT) [25, 26], the PES and PAD have not been tackled as control targets before. In fact, most previous studies did not even account for the presence of the ionization continuum. A proper representation of the ionization continuum becomes unavoidable [27–31], however, when investigating the interaction with XUV light where a single photon is sufficient to ionize [32], and it is indispensable for the full description of photoionization experiments.

To demonstrate the versatility of our approach, we apply it to two different control problems: (i) We prescribe the full three-dimensional photoelectron distribution and search for a field that produces, at least approximately, a given angle-integrated PES and energy-integrated PAD. Such a detailed control objective is rather demanding and corresponds to a difficult control problem. (ii) We seek to maximize the relative number of photoelectrons emitted into the upper as opposed to the lower hemisphere, assuming that the polarization axis of the light pulse runs through the poles of the two hemispheres. This implies a condition on the PAD alone, leaving complete freedom to the energy dependence. The corresponding control objective leaves considerable freedom to the optimization algorithm and the control problem becomes much simpler. Maximizing the relative number of photoelectrons emitted into the upper as opposed to the lower hemisphere

I. INTRODUCTION

Photoelectron spectroscopy is a powerful tool for studying photoionization in atoms, molecules and solids [1–6]. With the advent of new light sources, photoelectron spectroscopy using intense, short pulses has become available, revealing important information about electron dynamics and time-dependent phenomena [7–10]. In particular, it allows for characterizing the light-matter interaction of increasingly complex systems [1, 3, 5]. Photoelectron spectra (PES) and photoelectron angular distributions (PAD) contain not only fingerprints of the interaction of the electrons with the electromagnetic fields, but also of their interaction and their correlations with each other [11]. PAD in particular can be used to uncover electron interactions and correlations [12, 13].

Tailoring the pulsed electric field in its amplitude, phase or polarization allows to control the electron dynamics, with corresponding signatures in the photoelectron spectrum [14–18]. While it is natural to ask how the electron dynamics is reflected in the experimental observables—PES and PAD [14–18], it may also be interesting to see whether one can control or manipulate directly these observables by tailoring the excitation pulse. Moreover, one may be interested in certain features such as directed electron emission without analyzing all the details of the time evolution. This is particularly true for complex systems where it may not be easy to trace the full dynamics all the way to the spectrum. The question that we ask here is how to find an external field that steers the dynamics such that the resulting photoelectron distribution fulfills certain prescribed properties. Importantly, the final state of the dynamics does not need to be known. The desired features may be reflected in the angle-integrated PES, the energy-integrated PAD, or both.

To answer this question, we employ optimal con-
corresponds to a maximization of the PAD’s asymmetry. Asymmetric photoelectron distributions arising in strong-field ionization were studied previously for near-infrared few-cycle pulses where the effect was attributed to the carrier envelope phase [33, 34]. Here, we pose the question whether it is possible to achieve asymmetry in the PAD for multiphoton ionization in the XUV regime and we seek to determine the shaped pulse that steers the electrons into one hemisphere. To ensure experimental feasibility of the optimized pulses, we introduce spectral as well as amplitude constraints. We test our control toolbox for hydrogen and argon atoms, corresponding to a single channel and three active channels, respectively. These comparatively simple examples allow for a complete discussion of our optimization approach, while keeping the numerical effort at an acceptable level.

The remainder of this paper is organized as follows. Section II briefly reviews the methodology for describing the electron dynamics, with Sec. II A devoted to the TD-CIS method, and Sec. II B presenting the wave function splitting approach. Optimal control theory for photoelectron distributions is developed in Sec. III. Specifically, we introduce the optimization functionals to prescribe a certain PES plus PAD and to generate directed photoelectron emission in Sec. III A. The corresponding optimization algorithms are presented in Sec. III B, emphasizing the combination of OCT with the wave function splitting method. For the additional functionality of restricting the spectral bandwidth of the field in the optimization, the reader is referred to Appendix A. Our numerical results are presented in Sec. IV to VI, demonstrating, for hydrogen, the prescription of the PES and PAD in Sec. IV and the minimization of photoelectron emission into the lower hemisphere in Sec. V. Maximization of the relative number of photoelectrons emitted into the upper hemisphere is discussed for both hydrogen and argon in Sec. VI. Finally, Sec. VII concludes.

II. THEORY

In the following, we briefly review, following Refs. [20, 21], the theoretical framework for describing the electron dynamics and the interaction with strong electric fields.

A. First principles calculation of the \(N\)-particle wave function: TD-CIS

Our method for calculating the outgoing electron wave packet is based on the time-dependent configuration interaction singles (TD-CIS) scheme [20, 35]. The time-dependent Schrödinger equation of the full \(N\)-electron system,

\[
\frac{\partial}{\partial t} |\Psi(t)\rangle = \hat{H}(t) |\Psi(t)\rangle,
\]

is solved numerically using the Lanczos-Arnoldi propagator [36, 37]. To this end, the \(N\)-electron wave function is expanded in the one-particle–one-hole basis:

\[
|\Psi(t)\rangle = \alpha_0(t) |\Phi_0\rangle + \sum_{i,a} \alpha_i^a(t) |\Phi_i^a\rangle,
\]

where the index \(i\) denotes an initially occupied orbital, \(a\) stands for a virtual orbital to which the particle can be excited and \(|\Phi_0\rangle\) symbolizes the Hartree-Fock ground state. The full time dependent Hamiltonian has the form

\[
\hat{H}(t) = \hat{H}_0 + \hat{H}_1 + \hat{p} \cdot \mathbf{A}(t),
\]

where \(\hat{H}_0 = \hat{T} + \hat{V}_{\text{nuc}} + \hat{V}_{\text{MF}} - E_{\text{HF}}\) contains the kinetic energy \(\hat{T}\), the nuclear potential \(\hat{V}_{\text{nuc}}\), the potential at the mean-field level \(\hat{V}_{\text{MF}}\) and the Hartree-Fock energy \(E_{\text{HF}}\). \(\hat{H}_1 = \frac{1}{r_{\min}} - \hat{V}_{\text{MF}}\) describes the Coulomb interactions beyond the mean-field level, and \(\hat{p} \cdot \mathbf{A}(t)\) is the light-matter interaction within the velocity form in the dipole approximation, assuming linear polarization.

The TD-CIS approach is a multi-channel method, i.e., all ionization channels that lead to a single excitation of the system are included in the calculation. Since only states with total spin \(S = 0\) are considered, only spin singlets occur and we denote the occupied orbitals by \(|\phi_i\rangle\).

As introduced in Ref. [38], for each ionization channel all single excitations from the occupied orbital \(|\phi_i\rangle\) may be collected in one “channel wave function”:

\[
|\varphi_i(t)\rangle = \sum_a \alpha_i^a(t) |\phi_a\rangle
\]

where the summation runs over all virtual orbitals, labeled with \(a\), which is a multi-index [20]. These channel wave functions allow to calculate all quantities in a channel-resolved manner [21, 22]. In the actual implementation, the orbitals in Eq. (4) are expressed as a product of radial and angular parts [20, 21],

\[
\phi_a(r) = \frac{u_a^\alpha(r)}{r} Y_m^\ell(r, \varphi_r),
\]

where \(Y_m^\ell\) denote the spherical harmonics and \(u_a^\alpha(r)\) is the radial part of the wave function which is represented on a pseudo-spectral spatial grid [20].

B. The wave function splitting method

The PES and PAD are calculated using the splitting method [39] which was implemented within the TD-CIS scheme [21, 22]. Briefly, in this propagation approach the wave function is split into an inner and an outer part using a smooth radial splitting function,

\[
\hat{S} = \left[1 + e^{-(r - r_s)/\Delta}\right]^{-1},
\]

where the parameter \(\Delta\) controls how steep the slope of the function is and \(r_s\) is the splitting radius. The channel wave functions (4) are used to calculate the spectral
components in a channel-resolved manner by projecting the outer part onto Volkov states, $|p^V⟩ = (2\pi)^{-3/2}e^{ip·r}$. To this end, each channel wavefunction is split into an inner and an outer part at every splitting time $t_j,$

$$|φ_i(t_j)⟩ = |φ_{i,\text{in}}(t_j)⟩ + |φ_{i,\text{out}}(t_j)⟩$$

where

$$|φ_{i,\text{in}}(t_j)⟩ = (1 - S)|φ_i(t_j)⟩$$

and

$$|φ_{i,\text{out}}(t_j)⟩ = S|φ_i(t_j)⟩$$

At each splitting time, the inner part, $|φ_{i,\text{in}}(t_j)⟩,$ is represented in the CIS basis and further propagated with the full Hamiltonian (3), whereas the outer part is stored and propagated analytically to large times with the Volkov Hamiltonian,

$$\hat{H}_V(τ) = \frac{1}{2}[p + A(τ)]^2.$$  

In this way, the outer part of the wave function can be analyzed separately in order to obtain information on the photoelectron. Furthermore, since the outgoing part of the wave function is absorbed efficiently at the splitting times, large box sizes are avoided in the inner region.

The spectral coefficient $φ_i(p; T; t_j)$ for a given channel $i$, originating from splitting time $t_j$ and evaluated at the final time $t = T$ is obtained as a function of the momentum vector $p$ [21],

$$\varphi_{i,\text{out}}(p; T; t_j) = \int d^3p' (p^V)|\hat{U}_V(T, t_j)|p'^V⟩⟨p'^V|φ_{i,\text{out}}(t_j)⟩$$

where $\vartheta_V(p)$ denotes the Volkov phase, given by

$$\vartheta_V(p) = \frac{1}{2} \int_{t_j}^{T} dτ [p + A(τ)]^2,$$

the sum runs over the virtual orbitals, $β^a_i(t_j)$ is the overlap of the outer part with the virtual orbital,

$$β_i^a(t_j) = ⟨φ_a|φ_{i,\text{out}}(t_j)⟩,$$

and $j_l(x)$ is the $l$th Bessel function. $\hat{U}_V(t_2, t_1) = \exp \left( -i \int_{t_1}^{t_2} \hat{H}_V(τ) dτ \right)$ is the evolution operator associated with the Volkov Hamiltonian (8) and $T$ is a sufficiently long time so that all parts of the wave function that are of interest have reached the outer region and are included in the PES. The contributions from all splitting times must be added up coherently to form the total spectral coefficient for the channel $i$,

$$\varphi_{i,\text{out}}(p; T) = \sum_{t_j} \varphi_{i,\text{out}}(p; T; t_j).$$

Finally, incoherent summation over all possible ionization channels yields the total spectrum [21],

$$\frac{d^2σ(p)}{dp dΩ} = |\varphi_{\text{out}}(p; T)|^2 = \sum_i |\varphi_{i,\text{out}}(p, T)|^2.$$  

The energy-integrated PAD is given by integrating over energy or, equivalently, momentum,

$$\frac{dσ}{dΩ} = \int_0^{∞} \frac{d^2σ(p)}{dp dΩ} p^2 dp.$$

Analogously, the angle-integrated PES is obtained upon integration over the solid angle,

$$\frac{dσ}{dE} = p \int_0^{2π} \int_0^{π} \frac{d^2σ(p)}{dp dΩ} \sin θ dθ dϕ$$

with $p = \sqrt{2E}$. The optimizations considered below are based on these measurable quantities.

### III. OPTIMAL CONTROL THEORY

#### A. Optimization problem

Our goal is to find a vector potential, or control, $A(t)$, that steers the system from the ground state $|Ψ(t = 0)⟩ = |Φ_0⟩$, defined in Eq. (2), to an unknown final state $|Ψ(T)⟩$ whose PES and/or PAD display certain desired features. Such an optimization target is expressed mathematically as a final time functional $J_T[\varphi_{\text{out}}, \varphi_{\text{out}}^†]$ [19]. We consider two different final time optimization functionals in the following.

As a first example, we seek to prescribe the angle-integrated PES and energy-integrated PAD together. The corresponding final time cost functional is defined as

$$J_T^{(1)}[\varphi_{\text{out}}(T), \varphi_{\text{out}}^†(T)] = λ_1 \int (\tilde{σ}(p, T) - \tilde{σ}_0(p))^2 d^3 p,$$

where $\tilde{σ}(p, T) = d^2σ(p)/dp dΩ$ denotes the actual photoelectron distribution, cf. Eq. (13), $\tilde{σ}_0(p)$ stands for the target distribution, and $λ_1$ is a weight that stresses
the importance of \( J_T^{(1)}(\tilde{\varphi}_{\text{out}}, \tilde{\varphi}^\dagger_{\text{out}}) \) compared to additional terms in the total optimization functional. The goal is thus to minimize the squared Euclidean distance between the actual and the desired photoelectron distributions.

Alternatively, we would like to control the difference in the number of electrons emitted into the lower and upper hemispheres. This can be expressed via the following final-time functional

\[
J_T^{(2)}(\tilde{\varphi}_{\text{out}}(T), \tilde{\varphi}^\dagger_{\text{out}}(T)) = \lambda_{2}^{(-)} \int_0^{\pi/2} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp + \lambda_{2}^{(+)} \int_{\pi/2}^{\pi} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp + \lambda_{2}^{\text{tot}} \int_0^{\pi} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp,
\]

where the first and second term correspond to the probability of the photoelectron being emitted into the lower and upper hemisphere, whereas the third term is the total ionization probability. \( \lambda_{2}^{(-)}, \lambda_{2}^{(+)} \) and \( \lambda_{2}^{\text{tot}} \) are weights. The factor of \( 2\pi \) resulting from integration over the azimuthal angle has been absorbed into the weights. Directed emission can be achieved in several ways—one can suppress the emission of the photoelectron into the lower hemisphere, without imposing any specific constraint on the number of electrons emitted into the upper hemisphere. This is achieved by choosing \( \lambda_{2}^{(+)} = \lambda_{2}^{\text{tot}} = 0 \) and \( \lambda_{2}^{(-)} > 0 \). Alternatively, one can maximize the difference in the number of electrons emitted into the upper and lower hemispheres. To this end, the relative weights need to be chosen such that \( \lambda_{2}^{(+)} > 0 \) and \( \lambda_{2}^{(-)} < 0 \). If \( \lambda_{2}^{\text{tot}} = 0 \), the optimization seeks to increase the absolute difference in the number of electrons emitted into the upper and lower hemisphere. Close to an optimum, this may result in a strong increase in the overall ionization probability, accompanied by a very small increase in the difference, since only the complete functional is required to converge monotonically, and not each of its parts. This undesired behavior can be avoided by maximizing the relative instead of the absolute difference of electrons emitted into the upper and lower hemispheres. It requires \( \lambda_{2}^{\text{tot}} > 0 \), i.e., minimization of the total ionization probability in addition to maximizing the difference. Note that \( \lambda_{2}^{\text{tot}} \) could also be absorbed into the weights for the hemispheres,

\[
J_T^{(2)}(\tilde{\varphi}_{\text{out}}(T), \tilde{\varphi}^\dagger_{\text{out}}(T)) = \lambda_{2}^{(-)} \int_0^{\pi/2} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp + \lambda_{2}^{(+)} \int_{\pi/2}^{\pi} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp + \lambda_{2}^{\text{tot}} \int_0^{\pi} \sin \theta \, d\theta \int_0^{+\infty} \left| \tilde{\varphi}_{\text{out}}(p, T) \right|^2 p^2 \, dp,
\]

where \( \lambda_{2}^{(-)} = -|\lambda_{2}^{(+)}| + |\lambda_{2}^{\text{tot}}| \) and \( \lambda_{2}^{(-)} = |\lambda_{2}^{(-)}| + |\lambda_{2}^{\text{tot}}| \) are effective weights. Since \( \lambda_{2}^{(+)} < 0 \) and \( \lambda_{2}^{(-)} > 0 \) in order to maximize (minimize) emission into the upper (lower) hemisphere, the weights need to fulfill the condition \( |\lambda_{2}^{(+)}| > |\lambda_{2}^{\text{tot}}| \).

The complete functional to be minimized,

\[
J = J_T(\tilde{\varphi}_{\text{out}}(T), \tilde{\varphi}^\dagger_{\text{out}}(T)) + C[A],
\]

also includes constraints \( C[A] \) to ensure that the control remains finite or has a limited spectral bandwidth. The constraints may be written for the electric field \( E(t) \) associated with the vector potential \( A(t) \), even though the minimization problem is expressed in terms of \( A(t) \) and the dynamics is generated by \( \dot{H}[A] \), cf. Eq. (3). The relation between the vector potential \( A(t) \) and the electric field \( E(t) \) is given by

\[
A(t) = -\int_{t_0}^{t} E(\tau) \, d\tau ,
\]

with \( A(t_0) = 0 \). Without loss of generality, we can write

\[
C[A] = C_a[A] + C_\omega[A] + C_0[A],
\]

where the independent terms in the rhs. of Eq. (20) are defined below.

The first property that the optimized electric field must fulfill is that its integral over time vanishes, i.e.,

\[
\int_{t_0}^{T} E(t) \, dt = 0,
\]

which implies, according to Eq. (19), \( A(T) = A(t_0) = 0 \). Therefore, we choose initial guess fields with \( A(T) = A(t_0) = 0 \) and utilize

\[
C_a[A] = \lambda_a \int s^{-1}(t) \left| A(t) - A_{\text{ref}}(t) \right|^2 dt
\]

with \( s(T) = 0 \) to ensure that Eq. (21) is fulfilled. In Eq. (22), \( A_{\text{ref}}(t) \) and \( s(t) \) refer to a reference vector potential and a shape function, respectively, and \( \lambda_a \geq 0 \) is a weight that stresses the importance of \( C_a[A] \) compared to all other terms in the complete functional, Eq. (18). The shape function, \( s(t) \), can be used to guarantee that the control is smoothly switched on and off at the initial and final times.

A second important property of the optimized field is a limited spectral bandwidth. Typically, optimization without spectral constraints leads to pulses with unnecessarily broad spectra which would be very hard or impossible to produce experimentally. To restrict the bandwidth of the electric field, \( E(t) \), we construct a constraint \( C_\omega[A] \) in frequency domain,

\[
C_\omega[A] = \lambda_\omega \int \tilde{\gamma}(\omega)(|\tilde{E}(\omega)|^2 \, d\omega
\]

\[
= \lambda_\omega \int \tilde{\gamma}(\omega) \omega^2 |\tilde{A}(\omega)|^2 \, d\omega,
\]
with $\tilde{E}(\omega)$ being the Fourier transform of the field,

$$\tilde{E}(\omega) = \int E(t) e^{-i\omega t} \, dt .$$  \hspace{1cm} (24)

Constraints of the form of Eq. (23) were previously discussed in Refs. [40, 41]: The kernel $\tilde{g}(w)$ plays a role similarly to the inverse shape function $s^{-1}(t)$ in Eq. (22), that is, it takes large values at all undesired frequencies. Additionally, we assume that the symmetry requirement $\tilde{g}(\omega) = \tilde{g}(-\omega)$ is fulfilled, see Appendix A for details.

Finally, in view of experimental feasibility, we would also like to limit the amplitude of the electric field to reasonable values. To this end, we construct a constraint that penalizes changes in the first time derivative of $A(t)$. In fact, since $E(t) = -A(t)$, large values in the derivative of the vector potential translate into large amplitudes of the corresponding electric field $E(t)$. To avoid this, we adopt here a modified regularization condition [42] for $A(t)$, defining

$$C_e[A] = \lambda_c \int s^{-1}(t)|E(t)|^2 \, dt$$

$$= \lambda_c \int s^{-1}(t)|\dot{A}(t)|^2 \, dt .$$  \hspace{1cm} (25)

$C_e[A]$ plays the role of a penalty functional [42], ensuring the regularity of $A(t)$, and, as a consequence, penalizing large values on the electric field amplitude $E(t)$. The choice of the same $s^{-1}(t)$ in both Eq. (22) and Eq. (25) will simplify the optimization algorithm as shown below.

B. Krotov’s method combined with wave function splitting

Krotov’s method for quantum optimal control provides a recipe to construct monotonically convergent optimization algorithms, depending on the target functional and additional constraints, the type of equation of motion, and the power of the control in the light-matter interaction [19]. The optimization algorithm consists of a set of coupled equations for the update of the control, the forward propagation of the state and the backward propagation of the so-called co-state. This set of equations needs to be solved iteratively. The final-time target functional (or, more precisely, its functional derivative with respect to the propagated state, evaluated at the final time, which reflects the extremum condition on the optimization functional [43]) determines the “initial” condition, at final time, for the backward propagation of the co-state [19]. Additional constraints which depend on the control such as those in Eq. (20) show up in the update equation for the control [19, 41]. The challenge when combining Krotov’s method with the wave function splitting approach is due to the fact that splitting in the forward propagation of the state implies “glueing” in the backward propagation of the co-state. Here, we present an extension of the optimization algorithm obtained with Krotov’s method that takes the splitting procedure into account.

Evaluating the prescription given in Refs. [19, 41], we find for the update equation, with $k$ labeling the iteration step,

$$A^{(k+1)}(t) = A^{(k)}(t) + I^{(k+1)}(t)$$

$$- \frac{\tilde{\lambda}_w}{\lambda_a} s(t) A^{(k+1)} \ast h(t) + \lambda_c \dot{A}^{(k+1)}(t) ,$$  \hspace{1cm} (26a)

with $\tilde{\lambda}_w = \sqrt{2\pi \lambda_a}$. $A^{(k+1)} \ast h(t)$ denotes the convolution of $A^{(k+1)}$ and $h(t)$,

$$A^{(k+1)} \ast h(t) = \int A^{(k+1)}(\tau) h(t - \tau) \, d\tau$$  \hspace{1cm} (26b)

with $h(t)$ the inverse Fourier transform of $\tilde{h}(\omega) = \omega^2 \tilde{\gamma}(\omega)$. The second term in Eq. (26a) is given by

$$I^{(k+1)}(t) = \frac{s(t)}{\lambda_a} \mathfrak{Im} \left\{ \chi^{(k)}(t) \left| \frac{\partial H}{\partial A} \right| \Psi^{(k+1)}(t) \right\}$$

$$= \frac{s(t)}{\lambda_a} \mathfrak{Im} \left\{ \langle \chi^{(k)}(t) | \hat{p} | \Psi^{(k+1)}(t) \rangle \right\} ,$$  \hspace{1cm} (26c)

where $|\Psi^{(k+1)}(t)\rangle$ and $|\chi^{(k)}(t)\rangle$ denote the forward propagated state and backward propagated co-state at iterations $k+1$ and $k$, respectively. The derivation of Eqs. (26) is detailed in Appendix A. In order to evaluate Eqs. (26), the co-state obtained at the previous iteration, $|\chi^{(k)}(t)\rangle$, using the old control, $A^{(k)}(t)$, must be known. Its equation of motion is found to be [19]

$$i \frac{\partial}{\partial t} |\chi(t)\rangle = \hat{H}(t) |\chi(t)\rangle .$$  \hspace{1cm} (27a)

Just as $|\Psi(t)\rangle$ is decomposed into channels wavefunctions, cf. Eq. (4), so is the co-state. The “initial” condition at the final time $T$ is written separately for each channel,

$$|\tilde{\chi}_{i,\text{out}}(T)\rangle = - \frac{\partial J_T[\hat{\varphi}_{i,\text{out}}(T), \hat{\varphi}_{i,\text{out}}^\dagger(T)]}{\partial \hat{\varphi}_{i,\text{out}}(T)} .$$  \hspace{1cm} (27b)

Evaluation of Eq. (27b) requires knowledge of the outer part of each channel wavefunction, $|\hat{\varphi}_{i,\text{out}}(T)\rangle$, which is obtained by forward propagation of the initial state, including the splitting procedure. In what follows, $\hat{U}(t', \tau; A(t))$ denotes the evolution operator that propagates a given state from time $t = \tau$ to $t = t'$ under the control $A(t)$. We distinguish the time evolution operators for the inner part, $\hat{U}_\text{i}(t', \tau; A(t))$, generated by the full Hamiltonian, Eq. (3), and for the outer part, $\hat{U}_\text{v}(t', \tau; A(t))$, generated by the Volkov Hamiltonian, Eq. (8). For every channel, the total wavefunction is given by

$$|\varphi^{(k+1)}_i(t)\rangle = |\varphi^{(k+1)}_{i,\text{in}}(t)\rangle + |\varphi^{(k+1)}_{i,\text{out}}(t)\rangle ,$$  \hspace{1cm} (28)
which is valid for arbitrary times \( t \geq t_1 \) with \( t_1 \) the first splitting time. The second term in Eq. (28) reads

\[
|\hat{\varphi}_{r,\text{out}}^{(k+1)}(t)⟩ = \sum_{j=1}^{\lfloor t/t_1 \rfloor} |\varphi_{r,\text{out}}^{(k+1)}(t; t_j)⟩
\]

\[
= \sum_{j=1}^{\lfloor t/t_1 \rfloor} \hat{U}_T(t, t_j; A^{(k+1)}) |\varphi_{r,\text{out}}^{(k+1)}(t_j)⟩
\]

where \( |x⟩ = \max\{m \in \mathbb{Z}, m \leq x \} \). Equation (29) accounts for the fact that for \( t \geq t_2 \), all outer parts \( |\varphi_{r,\text{out}}^{(k+1)}(t; t_j)⟩ \) that originate at splitting times \( t_j \leq t \) must be summed up coherently. Propagation of all \( |\varphi_{r,\text{out}}^{(k+1)}(t; t_j)⟩ \) and continued splitting of \( |\varphi_i^{(k+1)}(t)⟩ \) eventually yields the state at final time, \( |\varphi_i^{(k+1)}(T)⟩ \). Its outer part is given by

\[
|\varphi_{r,\text{out}}^{(k+1)}(T)⟩ = \sum_{j=1}^{N} |\varphi_{r,\text{out}}^{(k+1)}(T; t_j)⟩
\]

where \( N \) denotes the number of splitting times utilized during propagation, and the last splitting time \( t_N \) is chosen such that \( t_N \leq T \). The best compromise between size of the spatial grid, time step and duration between two consecutive splitting times is discussed in Ref. [21].

Equation (27b) can now be evaluated: Since our final time functionals all involve the product \( \hat{\varphi}_{\text{out}}(p, T) \cdot \hat{\varphi}_{\text{out}}^*(p, T) = σ(p, T) \), Eq. (27b) can be written, at the \( k \)th iteration of the optimization, as

\[
\hat{\chi}_{i,\text{out}}^{(k)}(p, T) = \mu(p) \hat{\varphi}_{r,\text{out}}^{(k)}(p, T)
\]

where \( \mu(p) \) is a function that depends on the target functional under consideration. It becomes

\[
μ_1^{(k)}(p) = -2λ_1 \left( \hat{σ}^{(k)}(p, T) - \hat{σ}_0(p) \right)
\]

for \( J_{T_1}^{(1)} \) given in Eq. (15) and

\[
μ_2(p) = λ_2^+ \mathbb{1}_{\vartheta_+}(θ) + λ_2^- \mathbb{1}_{\vartheta_-}(θ)
\]

for \( J_{T_2}^{(2)} \) given in Eq. (16). The intervals \( \vartheta_- = [π/2, π] \) and \( \vartheta_+ = [0, π/2] \) denote the lower and upper hemispheres, respectively, and \( \mathbb{1}_{\vartheta_±}(θ) \) is the characteristic function on a given interval,

\[
\mathbb{1}_{\vartheta_±}(θ) = \begin{cases} 1 & \text{if } θ \in \vartheta_± \\ 0 & \text{if } θ \notin \vartheta_± \end{cases}
\]

with \( θ \in [0, π] \) the polar angle with respect to the polarization axis. According to Eqs. (1) and (27a), or, more precisely, since we do not consider intermediate-time constraints that depend on the state of the system [19], \( |Ψ(t)⟩ \) and its co-state \( |χ(t)⟩ \) obey the same equation of motion. For that reason, it is convenient to define inner and outer parts of \( |χ(t)⟩ \), analogously to the forward propagated state,

\[
|\chi_i^{(k)}(t)⟩ = |\chi_{i,\text{in}}^{(k)}(t)⟩ + |\chi_{i,\text{out}}^{(k)}(t)⟩
\]

with

\[
|\chi_{i,\text{out}}^{(k)}(T)⟩ = \sum_{j=1}^{N} |\chi_{i,\text{out}}^{(k)}(T; t_j)⟩.
\]

Eq. (32b) implies that also \( |\chi_{i,\text{out}}^{(k)}(T)⟩ \) is obtained by coherently summing up the contributions from all splitting times.

Conversely, the outer part of the co-state originating at the splitting time \( t_j \) and evaluated at the same time is given by

\[
\chi_{i,\text{out}}^{(k)}(p, t_j; t_j) = \mu(p) |\varphi_{r,\text{out}}^{(k)}(p, t_j; t_j)⟩.
\]

The next step is to construct the total co-state at an arbitrary time \( t \), \( |\chi_i^{(k)}(t)⟩ \), required in Eq. (26), from all \( |\chi_{i,\text{out}}^{(k)}(t; t_j)⟩ \) using Eq. (33). This is achieved by backward propagation and “glueing” inner and outer parts, as opposite to “splitting” during the forward propagation. However, when reconstructing the co-state by backward propagation, care should be taken to not to perform the “glue” procedure twice or more, at a given splitting time.

The backward propagation of the co-state is explicitly explained in what follows: Since at the final time \( T \), the total co-state is given by a coherent superposition of all outer parts originating at the splitting times \( t_j \), cf. Eq. (32b), it suffices to store all \( |\varphi_{r,\text{out}}^{(k)}(t; t_j)⟩ \) and apply Eq. (33) to evaluate \( |\chi_{i,\text{out}}^{(k)}(t; t_j)⟩ \). We recall that \( |\chi_{i,\text{out}}^{(k)}(t; t_j)⟩ \), respectively \( |\varphi_{r,\text{out}}^{(k)}(t; t_j)⟩ \), denote the outer part born exclusively at \( t = t_j \) and evaluated at the same splitting time. Once all outer parts of the co-state are evaluated at every splitting time using Eq. (33), \( |\chi_i^{(k)}(t)⟩ \) is obtained for all times \( t \) by backward propagation and “glueing”, with the additional care of not “glueing” twice or more. In detail, \( |\chi_{i,\text{out}}^{(k)}(t; t_N)⟩ \) is propagated backwards from \( t_N \) to \( t_{N-1} \) using the full CIS Hamiltonian, \( \hat{H} \), cf. Eq. (3). The resulting wave function at \( t = t_{N-1} \) is \( |\chi_i^{(k)}(t_{N-1})⟩ \). The outer part born exclusively at the splitting time \( t = t_{N-1} \) is obtained using Eq. (33), and the “composite” wave function \( |\chi_i^{(k)}(t_{N-1})⟩ \) is obtained by “glueing” \( |\chi_i^{(k)}(t_{N-1})⟩ \) and \( |\chi_{i,\text{out}}^{(k)}(t_{N-1}; t_{N-1})⟩ \),

\[
|\chi_i^{(k)}(t_{N-1})⟩ = |\chi_{i,\text{in}}^{(k)}(t_{N-1})⟩ + |\chi_{i,\text{out}}^{(k)}(t_{N-1}; t_{N-1})⟩.
\]

The procedure is now repeated: the composite co-state \( |\chi_i^{(k)}(t_{N-1})⟩ \) is propagated backwards from \( t = t_{N-1} \) to \( t = t_{N-2} \) using the full CIS Hamiltonian, resulting in \( |\chi_i^{(k)}(t_{N-2})⟩ \), and “glueing” yields the composite wave function at \( t = t_{N-2} \),

\[
|\chi_i^{(k)}(t_{N-2})⟩ = |\chi_{i,\text{in}}^{(k)}(t_{N-2})⟩ + |\chi_{i,\text{out}}^{(k)}(t_{N-2}; t_{N-2})⟩,
\]

with \( |\chi_{i,\text{out}}^{(k)}(t_{N-2}; t_{N-2})⟩ \) given by Eq. (33); and so on and so forth for all splitting times \( t_j \), until \( t = t_0 \), where \( t_0 \)}
refers to the initial time. During the backward propagation, as described above, the resulting co-state is stored in CIS basis. It gives by construction, at an arbitrary time \( t \), the first term in Eq. (32a). The second term in Eq. (32a) involving the outer parts “born” at the splitting times \( t = t_j \) and evaluated at \( t > t_j \) is merely given by forward propagating analytically all \( |\chi_{t_{\text{out}}}(t_j; t_j)\rangle \) using the Volkov Hamiltonian, and summing them up coherently according to Eq. (29). This allows to calculate the “total” co-state wavefunction at an arbitrary time \( t \), analogously to \( |\varphi_i(t)\rangle \). Finally, Eqs. (32a) and (28) allow for evaluating Krotov’s update equation for the control, Eq. (26), where the iteration label just indicates whether the guess, \( A^{(0)}(t) \), the old, \( A^{(k)}(t) \), or the new control, \( A^{(k+1)}(t) \), enter the propagation of \( |\chi_i(t)\rangle \) and \( |\varphi_i(t)\rangle \), respectively. A difficulty in solving the update equation for the control, is given by the fact that Eq. (26) is implicit in \( A^{(k+1)}(t) \). Strategies to overcome this obstacle depend on the additional constraints.

C. Additional constraints

Implicitness of Eq. (26) in \( A^{(k+1)}(t) \) for \( \lambda_\omega = \lambda_\epsilon = 0 \) can easily be circumvented by a zeroth-order solution, employing two shifted time grids, one for the states, which are evaluated at \( n \Delta t \), and another one for the control, which is evaluated at \( (n + 1/2) \Delta t \) [43]. However, for \( \lambda_\omega \neq 0 \), Eq. (26) corresponds to a second order Fredholm equation with inhomogeneity \( I^{(k+1)}(t) \) [41]. Numerical solution is possible using, for example, the method of degenerate kernels [41]. To this end, the inhomogeneity \( I^{(k+1)}(t) \), which depends on \( |\varphi^{(k+1)}(t)\rangle \) and thus on \( A^{(k+1)}(t) \), is first approximated to zeroth order by solving Eq. (26) with \( \lambda_\omega = 0 \) that is, without frequency constraints: and the resulting approximation \( I_0^{(k+1)}(t) \) is then used to solve the Fredholm equation. While an iterative procedure to improve the approximation of \( I^{(k+1)}(t) \) is conceivable, the zeroth order approximation was found to be sufficient in Refs. [40, 41]. Here, we adopt a slightly different procedure, in the sense that the Fredholm equation is not solved in time domain but in frequency domain. This allows us to treat the cases \( \lambda_\omega \neq 0 \) and \( \lambda_\epsilon \neq 0 \) on the same footing. It is made possible by assuming that \( s(t) \) in Eqs. (22) and (25) rises and falls off very quickly at the beginning and end of the optimization time interval. This judicious choice of \( s(t) \) together with the fact that the Fourier transform of a convolution of two functions in time domain, as encountered in Eq. (26), is the product of the functions in frequency domain, allows to approximate

\[
\left| \int s(t) G^{(k+1)}(t) e^{-i\omega t} dt - S_0 \int G^{(k+1)}(t) e^{-i\omega t} dt \right| \leq \epsilon,
\]

where \( \epsilon \) is a small, positive number and \( G^{(k+1)}(t) \) is defined as

\[
G^{(k+1)}(t) = A^{(k+1)} * h(t).
\]

A possible choice for \( s(t) \) to fulfill the condition (34) is

\[
s(t) = e^{-\beta(t-t_c)/2\sigma^2},
\]

where \( \sigma \) refers to the duration of the pulse centered at \( t = t_c \). If Eq. (34) is satisfied, we can easily take the Fourier transform of both sides of Eq. (26a) to get

\[
\tilde{A}^{(k+1)}(\omega) = \tilde{\tilde{A}}^{(k)}(\omega) + \tilde{I}^{(k+1)}(\omega) \left( 1 + \frac{\lambda_\omega}{\lambda_a} \omega^2 \gamma(\omega) + \frac{\lambda_\epsilon}{\lambda_a} \omega^2 \right)^{-1},
\]

with \( \tilde{A}^{(k+1)}(\omega) = \int \tilde{\tilde{A}}^{(k+1)}(\omega) e^{+i\omega t} d\omega/\sqrt{2\pi} \). Note that Eq. (37a) becomes exact if \( s(t) \) is constant. Approximating \( I^{(k+1)}(\omega) \) by its zeroth order solution analogously to Ref. [41], Eq. (37a) can be expressed as

\[
\tilde{A}^{(k+1)}(\omega) = \tilde{G}(\omega) \tilde{A}_0^{(k+1)}(\omega),
\]

where \( \tilde{A}_0^{(k+1)}(\omega) \) is the zeroth order solution of the updated control, found by solving Eq. (26) with \( \lambda_\omega = \lambda_\epsilon = 0 \),

\[
\tilde{A}_0^{(k+1)}(\omega) = \tilde{\tilde{A}}^{(k)}(\omega) + \tilde{I}_0^{(k+1)}(\omega),
\]

and \( \tilde{G}(\omega) \) is a transfer function given by

\[
\tilde{G}(\omega) = \left( 1 + \frac{\lambda_\omega}{\lambda_a} \omega^2 \gamma(\omega) + \frac{\lambda_\epsilon}{\lambda_a} \omega^2 \right)^{-1}.
\]

D. Summary of the algorithm

The complete implementation of the optimization within the time-splitting framework of the TDCIS method is summarized as follows:

1. Choose an initial guess for the vector potential, \( A^{(k=0)}(t) \).

2. Forward propagation of the state:

   (a) Propagate \( |\Psi^{(k=0)}(t = 0)\rangle \), cf. Eq. (2), from \( t = 0 \) until the first splitting time, \( t = t_1 \), in the CIS basis. We label the projection of the propagated state onto the channel wavefunctions defined in Eq. (4) by \( i = 1, 2, \ldots \), while \( i = 0 \) is reserved for the projection onto the Hartree-Fock ground state.

   (b) At \( t = t_1 \), apply the splitting function defined in Eq. (6) to obtain \( |\varphi_i^{(k)}(t_1)\rangle \) and \( |\varphi_{i,\text{out}}^{(k)}(t_1)\rangle \). Store the outer part in the CIS representation, before transforming \( |\varphi_i^{(k)}(t_1)\rangle \) to the Volkov representation.
(c) Propagate \( |\varphi^{(k)}_{i,in}(t_1)rangle \) using \( \hat{H} \) and 
\( |\varphi^{(k)}_{i,out}(t_1; t_1)rangle \) using \( \hat{H}_V \) from \( t = t_1 \) to the 
next splitting time \( t = t_2 \).

(d) At \( t = t_2 \), apply the splitting function to 
\( |\varphi^{(k)}_{i,in}(t_2)rangle \), again store the resulting outer 
part in CIS representation, and transform 
\( |\varphi^{(k)}_{i,out}(t_2; t_2)rangle \) to the Volkov representation.

(e) Propagate \( |\varphi^{(k)}_{i,in}(t_2)rangle \) using \( \hat{H} \) and 
\( |\tilde{\varphi}^{(k)}_{i,out}(t_2)rangle = |\varphi^{(k)}_{i,out}(t_2; t_1)+\varphi^{(k)}_{i,out}(t_2; t_2)rangle \) 
using \( \hat{H}_V \) from \( t = t_2 \) to the next splitting 
time \( t = t_3 \).

(f) Repeat steps (2d) and (2e) for all remaining 
splitting times \( t_j \) up to \( t_N \).

(g) Propagate for each channel wave function, 
\( |\tilde{\varphi}^{(k)}_{i,out}(t_N)rangle = \sum_{j=t}^{t_N} |\varphi^{(k)}_{i,out}(t_N; t_j)rangle \) from the 
last splitting time, \( t = t_N \), to the final time, 
\( t = T \), to obtain \( |\tilde{\varphi}^{(k)}_{i,out}(T)rangle \) and evaluate the 
target functional \( J_F \).

(h) Calculate \( \chi^{(k)}_{i,out}(p,T) \) according to Eq. (31a).

3. Backward propagation of the co-state:

(a) Calculate \( \mu(p,T) \) according to Eq. (31b) 
or (31c).

(b) Calculate \( |\chi^{(k)}_{i,in}(t_N; t_N)rangle \) from Eq. (33) and 
propagate it backwards using \( \hat{H} \) from \( t = t_N \) to the 
previous splitting time \( t_{N-1} \). The 
resulting state is \( |\chi^{(k)}_{i,in}(t_{N-1})rangle \).

(c) At \( t = t_{N-1} \), calculate \( |\chi^{(k)}_{i,out}(t_{N-1}; t_{N-1})rangle \) 
from Eq. (33) and ‘glue’ to obtain 
\( |\chi^{(k)}_{i,in}(t_{N-1})rangle = |\chi^{(k)}_{i,in}(t_{N-1})rangle + 
|\chi^{(k)}_{i,out}(t_{N-1}; t_{N-1})rangle \). This procedure is 
performed in the CIS basis for each channel 
wave function.

(d) Propagate \( |\chi^{(k)}_{i}(t_{N-1})rangle \) from \( t = t_{N-1} \) to \( t_{N-2} \) using 
\( \hat{H} \) to obtain \( |\chi^{(k)}_{i,in}(t_{N-2})rangle \).

(e) Repeat steps (3c) and (3d) for all remaining 
splitting times and propagate backward up to 
\( t = 0 \). During the backward propagation, the 
resulting wavefunction is stored in the CIS ba-
sis. As previously detailed, this procedure al-
 lows for performing the “glueing” procedure 
only once at every splitting time. It gives 
gives rises to the first term in Eq. (32a). The 
second term involving the evaluation of the 
outer part (coherent summation) at any ar-
tbitrary time \( t \) is obtained upon application 
Eq. (29) to each of the individual contribution 
\( |\chi_{i,out}(t_j; t_j)rangle \) for all splitting times.

4. Forward propagation and update of control:

(a) Determine the zeroth order approximation of 
the new control at times \( (n + 1/2)\Delta t \), 
\( A^{(k+1)}(n + 1/2\Delta t) \), from Eq. (26), using the 
states at times \( n\Delta t \), i.e., the co-state obtained 
in step 3, \( |\chi^{(k)}_{i}(n\Delta t)rangle \) and \( |\varphi^{(k+1)}_{i}(n\Delta t)rangle \) 
obtained with the control \( A^{(k+1)}((n-1/2)\Delta t) \).

(b) If \( \lambda_\omega \neq 0 \) or \( \lambda_e \neq 0 \), solve Eq. (37b) to obtain 
\( \hat{A}^{(k+1)}(\omega) \), using the approximated \( A^{(k+1)}(t) \), 
and Fourier transform \( \hat{A}^{(k+1)}(\omega) \) to time domain.

5. Increase \( k \) by one and repeat steps 3 and 4 until 
convergence of \( J_F \) is reached.

At this point, we would like to stress that the parameters 
chosen for the momentum grid require particular atten-
tion for the optimization algorithm to work. This is due 
to the transformation from the CIS representation to the 
Volkov basis (CIS–to–CIS transformation) at each splitting 
time, as discussed in Section II B. During the backward 
propagation, correspondingly, the inverse transformation 
is required, i.e., the \( p \)-to–CIS transformation. The \( \text{CIS–} 
\text{to–}\text{p} \) transformation of the outer part is evaluated using 
Eq. (9); the inverse of this transformation is straight-
forwardly derived. Since the dynamics is reversible, for-
dward propagation (involving wavefunction splitting and the 
CIS–to–p transformation) needs to give identical re-
results to backward propagation (involving wavefunction 
“glueing” and the \( p \)-to–CIS transformation). This can 
and needs to be used to check the numerical accuracy of the 
CIS–to–p transformation and its inverse: Since the 
inverse transformation involves integration over \( p \), a 
significant error is introduced if the sampling of the mo-
momentum grid is insufficient. Consequently, transforming 
the outer part from the CIS representation to the Volkov 
basis and then back may not yield exactly the same wave 
function. While for each \( p \)-to–CIS transformation the 
error may be relatively small, it accumulates as the opti-
imization proceeds iteratively according to Eq. (26). It 
results in optimized pulses with non-physical and unde-
sirable “jumps” at those splitting times where the accu-
ricy of the \( p \)-to–CIS transformation is insufficient and 
destroy the monotonic convergence of the optimization 
algorithm. The jumps disappear when the number of the 
momentum grid points is increased and \( p_{\text{max}} \) is adjusted.

Therefore, a naive solution to this problem would be to 
to considerably enlarge the number of momentum grid 
points. However, this will significantly increase the nu-
merical effort of the optimization, i.e., evaluation of the 
inner product in the rhs. of Eq. (26). The inner product 
involves not only calculation of the overlap of the inner 
part in the CIS representation and the outer part in the 
Volkov basis but it also requires evaluation of the mixed 
terms, \( \langle \chi^{(k)}_{i,in}(t) | \tilde{\varphi}^{(k+1)}_{i,out}(t) \rangle \) and 
\( \langle \chi^{(k)}_{i,in}(t) | \tilde{\varphi}^{(k+1)}_{i,in}(t) \rangle \) 
and thus one CIS–to–p transformation and integration 
over two—or perhaps even three—degrees of freedom at ev-
every time \( t \), for each channel \( i \) and in every iteration step.
$k + 1$. Thence, finding the best balance between efficiency and accuracy in the $p$–to–CIS transformation is essential for the proper functioning and feasibility of the optimization calculations. Also, reducing the total size of the radial coordinate while simultaneously increasing the number of splitting times translates into a more important number of evaluations of the inner product defined in Eq. (26c) in momentum representation. Below, we state explicitly the momentum grid parameters utilized in our simulations which allowed for a good compromise between efficiency and accuracy.

IV. APPLICATION I: PRESCRIBING THE COMPLETE PHOTOELECTRON DISTRIBUTION

We consider, as a first example, the optimization of the complete photoelectron distribution, cf. Eq. (15), for a hydrogen atom. The wavepacket is represented, according to Eq. (2), in terms of the ground state $|\Phi_0\rangle$ and excitations $|\Phi^{a}\rangle$. The calculations employed a pseudo-spectral grid with density parameter $\zeta = 0.50$ [20], a spatial extension of 200 a.u. and 800 grid points. All optimization calculations employed a linearly polarized electric field along the $z$ axis. This translates into a rotational symmetry of the photoelectron distribution along the $z$ axis. Therefore, only wave functions of the form $\Psi_{\text{out}} = \Psi_{\text{out}}(p, \theta)$ need to be considered. For the calculation of the spectral components, the outer parts of the wave functions were projected onto the Volkov basis, defined on a spherical grid in momentum representation $p$. For our calculations, we adopted an evenly spaced grid in $p$ as well as in the polar coordinate $\theta$. The size of the radial component of the spherical momentum grid was set to $E_{\text{max}} = 6$ a.u., sampled at 301 points. The same number of points was utilized for the polar coordinate. The splitting radius was set to $r_c = 50$ a.u., the total number of splitting times is $N = 3$ with a smoothing parameter $\Delta = 50$ a.u. [21]. The splitting procedure was applied every 30 a.u. of time. Finally, a total integration time of 120 a.u. with a time step of 0.05 a.u. was utilized for the time propagation.

We consider first the minimization of the functional $J^{(1)}[\varphi, \varphi']$ defined in Eq. (15). The goal is to find a vector potential $A_{z,\text{opt}}(t)$ such that the photoelectron distribution resulting from the electron dynamics generated by $A_{z,\text{opt}}(t)$ coincides with $\sigma_0(p)$ at every point $p$, cf. Eq. (15). For visualization convenience, we plot the angle-integrated PES and energy-integrated PAD, cf. Eq. (14), associated to “target” photoelectron distribution $\sigma_0(p)$, as shown by the solid-black lines in Figs. 1(a) and 1(b), respectively. To simplify the optimization, neither frequency restriction nor amplitude constraint on $E_z(t)$ is imposed, i.e., $\lambda_\omega = \lambda_e = 0$. The initial guess for the vector potential is chosen in such a way that the fidelity with respect to the target $\sigma_0(p)$ is poor, see the green dashed lines in Fig. 1. Despite the bad initial guess, the optimization quickly approaches the desired photoelectron distribution, converging monotonically, as expected for Krotov’s method.

![Fig. 1: Optimal control of the complete photoelectron distribution for a hydrogen atom: (a) angle-integrated PES, and (b) energy-integrated PAD. As the optimization proceeds iteratively, the actual photoelectron distribution approaches the desired one (black solid line) in both its energy dependence and angular distribution. The photoelectron distribution obtained with the guess field (green dashed lines) is far from the desired distribution.](image1)

![Fig. 2: Optimization of the full photoelectron distribution: (a) Guess field $E_z^{(0)}(t)$ chosen to start the optimization shown in Fig. 1 and (b) optimized electric field obtained after about 700 iterations. (c) The final time cost functional $J^{(1)}_f$ decreases monotonically, as expected for Krotov’s method.](image2)
is shown in Fig. 2(b): Compared to the initial guess, cf. Fig. 2(a), the amplitude of the optimized field is somewhat increased, and a high-frequency oscillation has been added. The monotonic convergence towards the target distribution in terms of angle-integrated PES and energy-integrated PAD is illustrated in Fig. 1. We can appreciate that the algorithm first tends to match all points with higher values, starting with the peak near 15 eV, while adjusting the remainder of the spectrum, with lower values, later in the optimization. The slow-down of convergence, observed in Fig. 2(c) after about 200 iterations, is typical for optimization methods that rely on gradient information alone: As the optimum is approached, the gradient vanishes. Such a slow-down of convergence can only be avoided by incorporating information from higher order derivatives in the optimization. This is rather non-trivial in the framework of Krotov’s method and beyond the scope of our current study.

V. APPLICATION II: MINIMIZING THE PROBABILITY OF EMISSION INTO THE UPPER HEMISPHERE

As a second application of our control toolbox, we are interested in minimizing the probability of emission into the upper hemisphere without imposing any specific constraint on the number of electrons emitted into the lower hemisphere. The final time cost functional is given by Eq. (16) with $\lambda_2 > 0$ and $\lambda_2 = 0$. We consider again a hydrogen atom and a linearly polarized electric field along the $z$-axis, using the same numerical parameters as in Section IV.

In contrast to the example discussed in Section IV, no particular expression for the target PES and PAD needs to be imposed—we only require the probability of emission into the upper hemisphere to be minimized regardless of the actual shape of angle-integrated PES and energy-integrated PAD. We employ the optimization prescription described in Section III B using Eq. (31c) in the final time condition for the adjoint state. As the optimization proceeds iteratively, the energy-integrated PAD becomes more and more asymmetric, see Fig. 3, minimizing emission into the upper hemisphere, as desired. The guess and optimized pulses are shown in Fig. 4(a) and (b). As illustrated by the solid green line in Fig. 3, the guess field was chosen such that it leads to a symmetric probability of emission for the two hemispheres. Again, monotonic convergence of the final time cost functional is achieved, cf. Fig. 4(c). At the end of the iteration procedure, the probability of emission into the upper hemisphere vanishes completely. As for the lower hemisphere, the emission probability initially remains almost invariant as the algorithm proceeds iteratively, see Fig. 3, while the probability of emission into the upper hemisphere decreases very fast, and monotonically, as expected. However, for a large number of iterations, the probability of emission into the lower hemisphere starts to decrease as well. After about 150 iterations it reaches an emission probability of $2.3 \times 10^{-4}$, that is two orders of magnitude smaller than for the guess pulse. Although our goal is only for the probability of emission into the upper hemisphere to be minimized, without specific constraints on the probability of emission into the lower hemisphere, the current results are completely consistent in terms of the optimization problem. More precisely, the optimization does exactly what the functional $J_{(2)}^{\text{T}}$, Eq. (16) with $\lambda_2 > 0$ and $\lambda_2 = 0$, targets. In fact, since the target functional depends on the upper hemisphere alone, then, by construction, the algorithm calculates the corrections to the field according to Eq. (26), regardless of how these changes affect the probability of emission into the lower hemisphere. To keep the probability of emission into the lower hemisphere constant or to maximize it, an additional optimization functional is required. This is investigated in the following section and defines the motivation for the maximization of the anisotropy of
VI. APPLICATION III: MAXIMIZING THE DIFFERENCE IN THE NUMBER OF ELECTRONS Emitted INTO UPPER AND LOWER HEMISPHERE

Finally we maximize the difference in probability for emission into the upper and the lower hemispheres. To this end, we construct the final-time cost functional such that it maximizes emission into the upper hemisphere while simultaneously minimizing emission into the lower hemisphere. This is expressed by the functional (16) where both weights are non-zero and have different signs, \( \lambda_2^{(+)} < 0 \) and \( \lambda_2^{(-)} > 0 \). The signs correspond to maximization and minimization, respectively. We consider this control problem for two different atoms—hydrogen as a one-channel case and argon as an example with three active channels [21]. The latter serves to underline the appropriateness of our methodology for quantum control of multi-channel problems.

Furthermore, in order to demonstrate the versatility of our optimal control toolbox in constraining specific properties of the optimized electric field, we consider the following options: (i) a spectral constraint, i.e., \( \lambda_\omega \neq 0 \) in Eq. (23), and (ii) the constraint to minimize fast changes in the vector potential, with \( \lambda_\alpha \neq 0 \) in Eq. (25). The latter is equivalent to avoiding large electric field amplitudes.

A. Hydrogen

We consider a hydrogen atom, interacting with an electric field linearly polarized along the z-axis, using the same numerical parameters as in Sec. IV. The optimization was carried out with and without restricting the spectral bandwidth of \( E_2(t) \). Figure 5(b) displays the symmetric energy-integrated PAD obtained with the Gaussian guess field, shown in Fig. 6(b), for which a central frequency \( \omega_0 = 27.2 \text{ eV} \) was used. For the optimization with spectral constraint, the admissible frequency components for \( E_2(t) \) are chosen such that \( |E_2(\omega)|^2 \leq \epsilon \) for all \( |\omega| \geq \omega_{\text{max}} \) with \( \omega_{\text{max}} = 5 \text{ a.u.} \approx 136.1 \text{ eV} \). This requirement translates into the penalty function \( \tilde{g}(\omega) \) shown in Fig. 7(c), for which we have used the form

\[
\tilde{g}(\omega) = \tilde{g}_0 \left( 1 - e^{-\omega/\alpha}^{2n} \right),
\]

where the parameters \( \alpha, n \) and \( \tilde{g}_0 \) must be chosen such that the term \( \lambda_\omega \tilde{g}(\omega) \) in the functional \( C_\omega[A] \) in Eq. (23) takes very large values in the region of undesired frequencies. For our first example, \( \alpha = 25, n = 6 \) and \( \tilde{g}_0 = 1 \) allows for strongly penalizing, and therefore filtering all undesirable frequency components above \( |\omega| \geq \omega_{\text{max}} \), as it is shown by the corresponding transfer function \( \tilde{G}(\omega) \), cf. Fig. 7(d). Note that it is not the weight \( \lambda_\omega \) alone that determines how strictly the spectral constraint is enforced; it is the ratio \( \lambda_\omega/\lambda_\alpha \) that enters in the transfer function \( \tilde{G}(\omega) \). This reflects the competition of the different terms in the complete optimization functional, Eq. (18).

As in the previous two examples, the optimization approach developed leads to monotonic convergence of the target functional, Eq. (16), with and without spectral constraint. This is illustrated in Fig. 6(a). Even though

\[
\text{FIG. 5: Maximizing, for a hydrogen atom, the difference in photoelectron emission into the upper and lower hemisphere: (a) The probability for emission into the upper hemisphere (0 \leq \theta \leq \pi/2) increases significantly as the optimization proceeds. Although the probability for emission with angles (\pi/2 \leq \theta \leq \pi) also grows somewhat, the overall difference increases. The energy-integrated PAD obtained with the guess pulse is shown in (b). Note the different y-axis scales in (a) and (b).}
\]

\[
\text{FIG. 6: Maximization of the anisotropy in the PAD for hydrogen: The target functional } J^{(2)}_T \text{, for the optimization shown in Fig. 5, measuring the difference in probability for emission into upper and lower hemisphere increases monotonically with } (\lambda_\omega \neq 0) \text{ and without } (\lambda_\omega = 0) \text{ spectral constraint (a). The guess field (green line) is shown in (b) together with the shape function } s(t) \text{ used in both optimizations. The optimized field obtained with the spectral constraint is displayed in (c).}
\]
sharp and high peaks in amplitude, beyond experimen-
field optimized without spectral constraint presents very
difference is observed for the two fields. While the electric
optimized with and without spectral constraints—a huge
hemisphere by almost three orders of magnitude. The
connected to the gain in emission probability for the north-
ern hemisphere by only about 10 per cent.

The peak amplitude of the optimized field is about one
order of magnitude larger than that of the guess field, cf.
Fig. 6(b) and (c). The increase in peak amplitude is con-
nected to the gain in emission probability for the northern
hemisphere by almost three orders of magnitude. The
optimized pulse thus ionizes much more efficiently than
the guess pulse. Figure 8(a) compares the electric fields
optimized with and without spectral constraints—a huge
difference is observed for the two fields. While the electric
field optimized without spectral constraint presents very
sharp and high peaks in amplitude, beyond experimen-
tal feasibility, the frequency-constrained optimized field is characterized by reasonable amplitudes and a much
smoother shape. The frequency components of the un-
constrained optimized field shown in Fig. 7(a) now become clear. Note that the difference in amplitude only appears during the first half of the overall pulse duration, see Fig. 8(a). It is a known feature of Krotov’s method to favor changes in the field in an asymmetric fashion; the feature results from the sequential update of the control, as opposed to a concurrent one [46].

Figure 8(b) shows the energy-integrated PAD obtained upon propagation with the two fields. One notes that,
although the probability of emission into the lower hemi-
sphere is larger for the unconstrained than for the con-
strained field, the same applies to the probability of emis-
sion into the upper hemisphere. Therefore the differ-
ence in the number of electrons emitted into upper and
lower hemisphere is in the end relatively close, which ex-
plains the behavior of the final-time functional observed
in Fig. 6(a). The electron dynamics generated by the
frequency-unconstrained field leads to a larger total prob-
bility of emission into both hemispheres, with respect
to that obtained with the frequency-constrained field, as
shown in Fig. 8(c). More precisely, propagation with the
unconstrained optimized field results in a total proba-
bility of emission of 0.27, i.e., probabilities of 0.23 and
$3 \times 10^{-2}$ for emission into the upper and lower hemi-
sphere, respectively. In comparison, a total probability of
emission of 0.26 is obtained for the frequency-constrained
field, with probabilities of emission into the upper and
lower hemispheres of 0.22 and $3.9 \times 10^{-2}$, respectively.

The fact that the spikes observed in the unconstrained
optimized field do not have any significant impact on the
asymmetry of the PAD can be rationalized by the short
timescale on which the intensity is very high. This time is too short for the electronic system to respond to the rapid variations of the field amplitude.

In order to rationalize how anisotropy of electron emission is achieved by the optimized field, we analyze in Fig. 9 the partial wave decomposition of the angle-integrated PES, comparing the results obtained with the guess field to those obtained with the frequency-constrained optimized field. Inspection of Fig. 9 reveals that upon optimization, there is a clear transition from distinct ATI peaks, Fig. 9(a), to a quasicontinuum energy spectrum, Fig. 9(b). Also, the optimized field enhances the contribution of states of higher angular momentum that have the same kinetic energy. In particular, the peaks for \( l = 5 \) are dramatically higher than in the PES obtained with the guess field. In fact, the symmetric case, cf. Fig. 9(a), shows an energy distribution of partial waves characterized by waves of the same parity at the same energy, whereas the asymmetric case reveals a partial wave distribution of opposite parity at the same energy, cf. Fig. 9(b). Figure 9 thus demonstrates that the desired asymmetry in the energy-integrated PAD is achieved through the mixing of various partial waves of opposite parity at the same energy. Interestingly, especially lower frequencies are mixed with a considerable intensity into the pulse spectrum which leads to higher final energies in the PES. Thus, more angular momentum states are mixed.

Next, we would like to constrain not only the frequency components but also the maximal field amplitude, as the maximal field amplitude of the electric field, shown in Fig. 6(c) is still important. To this end, we employ Eq. (37) for \( n_e > 0 \), which penalizes large changes on the derivative of the vector potential, cf. Eq. (25), and thus large values of the electric field amplitude. As can be seen in Fig. 10(a), the resulting optimized field is one order of magnitude smaller than that for which no amplitude restriction was imposed, cf. Fig. 6(c), and of the same order of magnitude as the guess field. Despite the constraint and as shown in Fig. 10(c), a perfect top-bottom asymmetry is obtained.

A common feature observed between the amplitude-unconstrained and constrained cases concerns the low frequencies appearing upon optimization, cf. Fig. 7(b) and Fig. 10(b), respectively. To quantify the role of the frequency components for achieving anisotropy, we start by suppressing all frequency components above 10 eV: the anisotropy of emission is preserved. On the other hand, removing frequencies below the XUV re-establish the initial symmetry of emission into both hemispheres. Therefore, in both cases the top-bottom asymmetry arises from low frequency components of the optimized field and is achieved through the mixing of various partial waves of opposite parity at the same energy.

We extend now our quantum control multi-channel approach to the study of electron dynamics in argon, interacting with an electric field linearly polarized along the \( z \)-direction. We consider the 3s and 3p orbitals to contribute to the ionization dynamics and define three ionization channels 3s, 3p with \( m = 0 \) and 3p with \( m = +1 \) (the case 3p with \( m = -1 \) is symmetric to \( m = +1 \) due to the polarization direction of the electric field, linearly polarized along the \( z \) axis). In order to describe the multi-channel dynamics, a spatial grid of 100 a.u. with 450 grid points and a density parameter of \( \zeta = 0.55 \) was utilized. The size of the radial component of the spherical momentum grid was set to \( E_{max} = 12 \) a.u., sampled by 601 evenly spaced points, while the polar component \( \theta \in [0, \pi] \) was discretized using 301 points. A splitting radius of \( r_c = 50 \) a.u., and a smoothing parameter \( \Delta = 10.0 \) a.u. were employed, together with a splitting step of 2.0 a.u. and a total number of \( N_s = 2036 \) splitting times. For time propagation, the time step was chosen to be 0.01 a.u., for an overall integration time \( \Delta T \approx 200 \) a.u.

Analogously to the results shown for hydrogen in Sec. VI.A, the goal is to maximize the difference in the probability for electron emission into the upper and lower hemispheres. To start the optimization, a Gaussian-shaped guess electric field with central frequency \( \omega = \)}
The total emission probability amounts to only $1.4 \times 10^{-2}$. In order to obtain reasonable pulses which result in a maximally anisotropic PAD, we utilize Eq. (25) with $\lambda_{e} \neq 0$ to minimize fast changes in the vector potential and avoid large peaks of the electric field amplitude.

The optimized pulses for two values of the ratio $\lambda_{c}/\lambda_{a}$, characterizing the relative weight of minimizing peak values in the electric field compared to minimizing the integrated vector potential, are shown in Figs. 11(b) and (c), respectively. As expected, a larger amplitude constraint yields an electric field with a smaller maximal amplitude. In fact, the maximal amplitude for $\lambda_{c}/\lambda_{a} = 0.01$ is one order of magnitude larger than that of the guess field, whereas for $\lambda_{c}/\lambda_{a} = 0.02$ it is only three times larger. Figures 12(b) and (c) display the energy-integrated PADs obtained with these fields. A significant top-bottom asymmetry of emission is achieved in both cases, the main difference being the total emission probability of $2.7 \times 10^{-2}$ for Fig. 12(b) compared to $9.4 \times 10^{-3}$ for Fig. 12(c). The spectra of the two optimized fields are examined in Fig. 13. Despite the difference in amplitude, both optimized fields are characterized by low frequency components. Note that no frequency restriction was imposed. This finding suggests that the low frequency components are responsible for achieving the top-bottom asymmetry. Indeed, removing all optical and infra-red (IR) components results in a complete loss of the asymmetry. On the other hand, removing frequency components above 10 eV does not affect the top-bottom asymmetry achieved by both optimized fields considerably.

These optimization results raise the question whether frequency components in the optical and IR range are essential for achieving the top-bottom asymmetry or whether a pure XUV field can also realize the desired control. To answer this question, we now penalize all frequency components in the optical and IR region. The resulting optimized electric field and its spectrum are depicted in Fig. 14(a) and (b), respectively. This field indeed possesses frequency components only in the XUV

FIG. 10: Maximizing the anisotropy of photoelectron emission for hydrogen: Optimization results obtained when simultaneously constraining the maximal amplitude and frequency components of the electric field for the weights $|\lambda_{eff}^{(+)}| = 2|\lambda_{eff}^{(-)}|$ with $|\lambda_{eff}^{(+)}/+\lambda_{eff}^{(-)}|= 1$. A perfect anisotropy of emission is obtained.

FIG. 11: Maximizing, for an argon atom, the difference in photoelectron emission into the upper and lower hemisphere: Guess field (a) utilized for the optimization. Optimized fields obtained with an amplitude constraint are depicted in (b) and (c) respectively.

FIG. 12: Maximization of the top-bottom asymmetry in argon: Energy-integrated PAD obtained with the guess pulse (a) and amplitude-constrained cases with $|\lambda_{eff}^{(-)}| = 2|\lambda_{eff}^{(+)}|$ and $|\lambda_{eff}^{(+)}/+\lambda_{eff}^{(-)}|= 1$ in (b) and (c), respectively. Note the different scales for the probability of emission.
To avoid numerical instabilities when evaluating the emission is achieved by absorbing low-energy photons at relatively high intensity which is accompanied by strong mixing of a number of partial waves of opposite parity at the same energy. The same mechanism had previously been found for hydrogen, cf. Section VIA.

As for the optimized XUV electric field yielding an asymmetric probability for emission, shown in Fig. 14(c), the same mechanism involving mixing of partial waves of different parity at the same energy is found, cf. Fig. 16(b). Nevertheless, a much smaller number of partial waves is involved, cf. Fig. 16(a) and (b). For the XUV pulse (Fig. 14(b)), it is mainly the components of the continuum wavefunction with angular momentum \( l = 2 \) and \( l = 3 \) that contribute to the anisotropy of emission.

The reason why partial waves with different parity are always present for anisotropic photoelectron emission can be straightforwardly understood. It lies in the fact that the angular distribution arises from products of spherical harmonics, cf. Eqs. (14a), (13) and (9), and the product of two spherical harmonics with the same (opposite) parity is a symmetric (antisymmetric) function of \( \theta \). The optimized pulses take advantage of this property and realize the desired asymmetry by driving the dynamics in such a way that it results in partial wave components which interfere constructively (destructively) in the upper (lower) hemisphere.

We have also investigated whether channel coupling
plays a role in the generation of the anisotropy. While switching off the interchannel coupling in the dynamics under the optimized pulse shown in Fig. 14(a) decreases the resulting anisotropy slightly, overall it still yields an anisotropic PAD. This shows that interchannel coupling in argon is not a key factor in achieving top-bottom asymmetry in photoelectron angular distributions.

VII. CONCLUSIONS

To summarize, we have developed a quantum optimal control toolbox to target specific features in photoelectron spectra and photoelectron angular distributions that result from the interaction of a closed-shell atom with strong XUV radiation. To this end, we have combined Krotov’s method for quantum control [19] with the time-dependent configuration interaction singles approach to treat the electron dynamics [20] and the wave-function splitting method to calculate photoelectron spectra [21, 22]. We have presented here the algorithm and its implementation in detail. To the best of our knowledge, our work is the first to directly target photoelectron observables in quantum optimal control.

We have utilized this toolbox to identify, for the benchmark systems of hydrogen and argon atoms, photoionization pathways which result in asymmetric photoelectron emission. Our optimization results show that efficient mechanisms for achieving top-bottom asymmetry exist in both single-channel and multi-channel systems. We have found the channel coupling to be beneficial, albeit not essential for achieving asymmetric photoelectron emission. Since typically the solution to a quantum control problem is not unique, additional constraints are useful to ensure certain desired properties of the control fields, such as limits to peak amplitude and spectral width. We have demonstrated how such constraints allow to determine solutions characterized by low or high photon frequency. In the low frequency regime, our control solutions require relatively high intensities. Correspondingly, the anisotropy of the photoelectron emission is realized by strong mixing of many partial waves. In contrast, for pure XUV pulses, we have found low to moderate peak amplitudes to be sufficient for asymmetric photoelectron emission. In both cases, we have identified the top-bottom asymmetry to originate from mixing, in the photoelectron wavefunction, various partial waves of opposite parity at the same energy. The corresponding constructive (destructive) interference pattern in the upper (lower) hemisphere yields the desired asymmetry of photoelectron emission. Whereas many partial waves contribute for control fields characterized by low photon energy and high intensity, interference of two partial waves is found to be sufficient in the pure XUV regime. In all our examples, we have found surprisingly simple shapes of the optimized electric fields. In the case of hydrogen, tailored electric fields to achieve asymmetric photoelectron emission have been discussed before and we can compare our results to those of Refs. [34, 49]. Our work differs from these studies in that we avoid a parametrization of the field and allow for complete freedom in the change the electric field, whereas Refs. [34, 49] considered only the carrier-envelope phase, intensity and duration of the pulse as control knobs. The additional freedom of quantum optimal control theory is important, in particular when more complex systems are considered.

The set of applications that we have presented here is far from being exhaustive, and our current work opens many perspectives for both photoionization studies and quantum optimal control theory. On the one hand, we have shown how to develop optimization functionals that target directly an experimentally measurable quantity obtained from continuum wavefunctions. On the other hand, since our approach is general, it can straightforwardly be applied to more complex examples. In this respect it is desirable to lift the restriction to closed-shell systems. This would pave the way to studying the role of electron correlation in maximizing certain features in the photoelectron spectrum. Similarly, allowing for circular or elliptic polarization of the electric field, one could envision, for example, to maximize signatures of chirality in the photoelectron angular distributions. This requires, however, substantial further development on the level of

Appendix A: Frequency and Amplitude Restriction

In the following, we present the derivation of Krotov’s update equation for the control, Eq. (26a) using the approximation for \( s(t) \) previously described. This allows for a more compact expression for Krotov’s equation for the specific constraints on the field used in this work. It is obtained following Ref. [19]: We seek to minimize the complete functional, Eq. (18). In order to evaluate the extremum condition, we start by evaluating the functional derivative of the penalty functional with respect to the changes in the control field \( \mathbf{A}(t) \) in Eq. (22),

\[
\frac{\delta C_a[\mathbf{A}]}{\delta \mathbf{A}(t)} = 2 \lambda_a s^{-1}(t) (\mathbf{A}(t) - \mathbf{A}_{\text{ref}}(t)) . \tag{A1}
\]

Next, we evaluate the functional derivative of Eq. (23). Abbreviating \( \omega^2 \tilde{\gamma}(\omega) \) by \( \tilde{h}(\omega) \) in Eq. (23), the functional derivative reads

\[
\frac{\delta C_a[\mathbf{A}]}{\delta \mathbf{A}(t)} = \lambda_\omega \int \mathbf{A}^*(\omega) \frac{\delta \mathbf{A}(\omega)}{\delta \mathbf{A}(t)} \tilde{h}(\omega) \, d\omega \\
+ \lambda_\omega \int \mathbf{A}(\omega) \frac{\delta \mathbf{A}^*(\omega)}{\delta \mathbf{A}(t)} \tilde{h}(\omega) \, d\omega . \tag{A2}
\]

Using the fact that \( \mathbf{A}(\omega) \) is the Fourier transform of \( \mathbf{A}(t) \),

\[
\mathbf{A}(\omega) = \int \mathbf{A}(t) e^{-i\omega t} \, dt ,
\]

the functional derivative becomes,

\[
\frac{\delta \mathbf{A}(\omega)}{\delta \mathbf{A}(t)} = e^{-i\omega t} ,
\]

such that

\[
\frac{\delta C_a[\mathbf{A}]}{\delta \mathbf{A}(t)} = \lambda_\omega \int \mathbf{A}^*\omega) e^{-i\omega t} \tilde{h}(\omega) \, d\omega \\
+ \lambda_\omega \int \mathbf{A}(\omega) e^{i\omega t} \tilde{h}(\omega) \, d\omega .
\]

This can be rewritten as

\[
\frac{\delta C_a[\mathbf{A}]}{\delta \mathbf{A}(t)} = \lambda_\omega \int \mathbf{A}^*(-\omega) e^{i\omega t} \tilde{h}(-\omega) \, d\omega \\
+ \lambda_\omega \int \mathbf{A}(\omega) e^{i\omega t} \tilde{h}(\omega) \, d\omega . \tag{A3}
\]

Since the control \( \mathbf{A}(t) \) is a real function of time, \( \mathbf{A}^*(-\omega) = \mathbf{A}(\omega) \). Moreover, by construction \( \tilde{h}(\omega) = \tilde{h}(-\omega) \). Therefore, Eq. (A3) becomes

\[
\frac{\delta C_a[\mathbf{A}]}{\delta \mathbf{A}(t)} = 2 \lambda_\omega \int \mathbf{A}(\omega) e^{+i\omega t} \tilde{h}(\omega) \, d\omega \tag{A4}
= 2 \lambda_\omega \int \mathbf{A}(\omega) e^{i\omega t} \, d\omega \int \mathbf{h}(\tau) e^{-i\omega \tau} \, d\tau \\
= 2 \lambda_\omega \int \mathbf{h}(\tau) d\tau \int \mathbf{A}(\omega)e^{i\omega(t-\tau)} \, d\omega \\
= 2 \lambda_\omega \int \mathbf{h}(\tau) \mathbf{A}(t-\tau) \, d\tau = 2 \lambda_\omega \mathbf{A} * \mathbf{h}(t) ,
\]

with \( \tilde{\lambda}_\omega = \sqrt{2\pi} \lambda_\omega \), and \( \mathbf{h}(\tau) = \int \tilde{h}(\omega) \exp(\pm i\omega \tau) \, d\omega / \sqrt{2\pi} \) and where \( f * g(t) \) refers to the convolution product of \( f \) and \( g \).

We now calculate the functional derivative of the constraint penalizing large values of \( \mathbf{A}(t) \), Eq. (25). Assuming vanishing boundary conditions for \( \mathbf{A}(t) \), we find, upon integration by parts,

\[
\frac{\delta C_c[\mathbf{A}]}{\delta \mathbf{A}(t)} = -2 \lambda_c s^{-1}(t) \mathbf{A}(t) . \tag{A5}
\]

Using Eqs. (A1), (A4) and (A5), the extremum condition with respect to a variation in the control becomes

\[
0 = \lambda_\omega s^{-1}(t) (\mathbf{A}(t) - \mathbf{A}_{\text{ref}}(t)) - \lambda_c s^{-1}(t) \mathbf{A}(t) \\
+ \tilde{\lambda}_\omega \mathbf{A} * \mathbf{h}(t) - \mathfrak{Im} \left\{ \chi(t) \left| \frac{\partial \mathcal{H}}{\partial \mathbf{A}} \right| \Psi(t) \right\} .
\]

where the last term has been previously introduced in Eq. (26). It can be straightforwardly derived from variational principles, i.e. Euler-Lagrange Lagrange equation, or in the context of Pontriagin’s maximum/minimum principle or in the context of Krotov’s optimization method, cf. Refs. [19, 41]. It stresses the dynamics to which the forward propagated state is subject to. Solving for \( \mathbf{A}(t) \) gives us the update rule for the optimized pulse,

\[
\mathbf{A}(t) = \mathbf{A}_{\text{ref}}(t) + \frac{s(t)}{\lambda_\omega} \mathfrak{Im} \left\{ \chi(t) \left| \frac{\partial \mathcal{H}}{\partial \mathbf{A}} \right| \Psi(t) \right\} \\
- \frac{\tilde{\lambda}_\omega}{\lambda_\omega} s(t) \mathbf{A} * \mathbf{h}(t) + \frac{\lambda_c}{\lambda_\omega} \mathbf{A}(t) , \tag{A6}
\]

i.e., we retrieve Eq. (26a). Using the property

\[
\int \mathbf{A}(t) e^{-i\omega t} \, dt = -\omega^2 \mathbf{A}(\omega) ,
\]

together with Eq. (36) for \( s(t) \), it is straightforward to write Krotov’s equation in frequency domain. To this end, we merely take the Fourier transform of Eq. (A6) and utilize the well-known property that the Fourier transform of a convolution of two functions in time domain is the product of the functions in frequency domain.
We thus find
\[ \tilde{A}^{(k+1)}(\omega) \approx \tilde{A}^{(k)}(\omega) + \tilde{I}^{(k+1)}(\omega) \]

\[ -\frac{\lambda}{\lambda_0} \tilde{A}^{(k+1)}(\omega) \tilde{h}(\omega) - \omega^2 \frac{\lambda}{\lambda_0} \tilde{A}^{(k+1)}(\omega), \]
which yields Eq. (37a).
