INTRODUCTION

Epilepsy is a chronic neurological disorder characterized by spontaneous recurrent seizures. Status epilepticus (SE) is a seizure that persists for 20 to 30 minutes or repeats without recovery (1). About 1-2% of people suffer from various epileptic diseases and treatment is not effective for 20-40% of the patients with epilepsy (2). In addition, previous investigators have reported excitotoxic injury, necrosis, and programmed apoptotic cell death in the brain induced by epilepsy (3). In the mouse pilocarpine-induced SE model massive neurodegenerative lesions were detected in the brain subregions including the hippocampus and cerebral cortex (4). Behavioral and cognitive disorders have been observed in epileptic animal models, as well as in patients, as a result of seizure-induced neuronal damage (5, 6). Moreover, cognitive impairment by significant olfactory dysfunction was frequently detected in patients with temporal lobe epilepsy (7).

The olfactory circuitry has been studied for over a hundred years and its well-defined structure and connections have been recently clarified (8). The olfactory bulb has a highly layered structure containing dendrodendritic synapses of various neurons and is regarded as a favorable region for morphological, electrophysiological and biochemical analyses (9). In a previous study, parvalbumin (PV) immunoreactivity was detected in the γ-aminobutyric acid (GABAergic interneurons in the external plexiform layer (EPL) and glomerular layer (GL) of the main olfactory bulb (MOB) and PV expression was decreased with aging (9). Calcium-binding proteins, including PV, modulate Ca2+ concentrations that are crucial for diverse cellular events, such as synaptic transmission, cell division, neurite outgrowth and neurodegeneration (10-12). In the nervous system, PV is known to be expressed on fast-spiking GABAergic interneurons in the external plexiform layer (EPL) and glomerular layer (GL) of the main olfactory bulb (MOB) and PV expression was decreased with aging (9). Calcium-binding proteins, including PV, modulate Ca2+ concentrations that are crucial for diverse cellular events, such as synaptic transmission, cell division, neurite outgrowth and neurodegeneration (10-12). In the nervous system, PV is known to be expressed on fast-spiking GABAergic interneurons in the external plexiform layer (EPL) and glomerular layer (GL) of the main olfactory bulb (MOB) and PV expression was decreased with aging (9). Calcium-binding proteins, including PV, modulate Ca2+ concentrations that are crucial for diverse cellular events, such as synaptic transmission, cell division, neurite outgrowth and neurodegeneration (10-12).
logical changes in PV-positive interneurons in pathological states such as SE. Therefore, in the present study, we investigated the expression of PV in the subregions of the main olfactory bulb to identify a correlation between morphological changes in PV-positive interneurons and the functional loss of olfaction following SE.

RESULTS

Neuronal degeneration in the MOB after pilocarpine administration
To evaluate the neuronal degeneration in the pilocarpine-induced SE model, we performed Fluoro-jade b (FJB) staining in the control and pilocarpine-induced SE rat groups. The structure of the main olfactory bulb is described in Fig. 1A (George Paxinos and Charles Watson) and we focused on changes in FJB staining in the EPL and GL. In the control group, a few FJB-positive cells were detected in the EPL and GL of the MOB (Fig. 1B1 and C1). However, six hours after pilocarpine treatment, the number of FJB-positive cells was significantly increased in both the EPL and GL zones of the MOB compared to the control group (Fig. 1B2, C2, D and E). In addition, the elevated numbers of FJB-positive cells were still present at three months, as the period of recurrent seizures, after the induction of SE by pilocarpine treatment (data not shown).

Fig. 1. Structure of the rat main olfactory bulb (MOB) adapted from the Rat Brain in Stereotaxic Coordinates (George Paxinos and Charles Watson) (A). Neuronal degeneration in the EPL (B) and GL (C) of the MOB in the control and 6 h after SE. The FJB positive cells expression is significantly increased in the EPL and GL regions compared to the control (D and E). All data are presented as mean ± SEM. ***P < 0.005 vs. control. glom-erular layer; GL, external plexiform layer; EPL, mitral cell layer; Mi, internal plexiform layer; Gi, granule cell layer of accessory olfactory bulb; GrA, H; hours, M; months. Scale bar = 17 μm.

Altered PV immunoreactivity in the MOB following SE
Immunohistochemistry for PV was performed to identify the expression and morphological changes in PV-positive interneurons in the EPL and GL of the MOB. In the control group, PV immunoreactivity was observed in neuronal somas and processes and the average number of PV-positive interneurons was 16.75 per 250 × 250 μm² in the EPL (Fig. 2A1 and 2D1). However, PV immunoreactivity in the 6 hour group after pilocarpine was remarkably decreased in the neuronal processes rather than in the somas, and the average number of PV-positive interneurons was reduced in the EPL compared to the control group (Fig. 2B1, D1, and E1). In addition, three months after pilocarpine treatment, the number of PV-positive interneurons was severely decreased in the EPL compared to six hours after pilocarpine treatment (Fig. 2C1, D1, and E1). Similar to the results observed in the EPL area, the expression of PV-positive interneurons in the GL gradually declined with time following the induction of SE. The distribution of PV-immunoreactive interneurons six hours following SE was remarkably decreased in the GL region of the MOB compared to the control and decreased expression was also observed in the dendritic processes (Fig. 2A2, B2, D2, and E2). Three months after pilocarpine treatment, PV immunoreactivity was barely detectable at the recurrent seizure time period following SE (Fig. 2C2, D2, and E2). Moreover, immunoblot analysis of PV expression showed results similar to the immunohistochemical data (Fig. 2F1 and F2).

Effects of long-term epilepsy on NeuN and MAP2 immunoreactivity
To identify the correlation between the neuronal loss in PV-positive and NeuN-positive cells, double immunofluorescence staining for these fast-spiking GABAergic interneurons and neuronal markers, respectively, was performed. In the control group, the PV immunoreactivity in the NeuN-positive neurons was widespread and distinctly detected in the EPL of the MOB (Fig. 3A1 - D1). However, six hours after SE induction by pilocarpine treatment, the double-labeled expression of PV and NeuN was reduced in the EPL compared to the control levels (Fig. 3A2 - D2). The quantitative analyses of the immunofluorescence staining results for these two markers were similar (Fig. 3E1). The expression of PV and NeuN was lower after three months of recurrent seizures than six hours after pilocarpine treatment (Fig. 3A3 - D3), which was supported by the quantitative analysis of the immunofluorescence staining (Fig. 3E1). Similar to the results in the EPL following SE, in the GL, double-labeled PV- and NeuN-positive interneurons were seen in the same patterns within the EPL six hours after SE, but not in the control groups (Fig. 3A4 - D4 and A5 - D5). The quantitative analysis was consistent with the immunofluorescence data (Fig. 3E2). The PV and NeuN immunoreactive interneurons had disappeared three months following pilocarpine (Fig. 3A6 - D6) and the percentage of PV- and NeuN-positive interneurons was also downregulated (Fig. 3E2).

To identify the structural changes in the dendritic processes of the PV-positive interneurons, we performed double immunofluorescence staining with MAP2. In the control group, MAP2 was densely expressed in the dendrites of the PV-positive interneuronal population in the entire EPL and GL regions of the MOB (Fig. 4A1 and A2), while in the 6 hours pilocarpine group, MAP2 was significantly decreased in the EPL and GL areas (Fig. 4B1 and B2). The quantitative analysis of MAP2 expression was consistent with the decrease in the double-labeled PV-positive interneurons (Fig. 4C1 and C2), and there was a remarkable decrease in MAP2 expression in the GL compared to the EPL (Fig. 4A1 and A2 vs. B1 and B2). Three months after pilocarpine treatment, MAP2 expression was further decreased in both the EPL and GL areas, which was consistent with the long-term effects of SE on the MOB (Fig. 4A3 and A4 vs. B3 and B4).
PV immunoreactivity in the MOB following SE
Yeon Hee Yu, et al.

Fig. 2. Immunohistochemistry for PV in the EPL and GL of the MOB in the control (A), 6 h (B), and 3 M (C) groups following SE. In the control group, PV immunoreactivity is detected in the somas and processes (A1-A2). After SE, PV immunoreactivity is markedly decreased both in the EPL and GL (B1-B2, C1-C2, D, and E). All data are presented as mean ± SEM. *P < 0.05, **P < 0.01 vs. control. Glomerular layer; GL, external plexiform layer; EPL, H; hours, M; months. Scale bar = 17 μm. Western blot analysis of PV antibody in MOB following SE (F1). Lane 1, control; Lane 2, 6 hr after SE; Lane 3, 3 month after SE. Optical density (O.D.) analyses of PV protein levels in the MOB (F2). All data are presented as mean ± SEM. *P < 0.05, ***P < 0.005, vs. control. H; hours, M; months.

Fig. 3. Double immunofluorescence staining for PV (A, green), NeuN (B, red), with DAPI (C), and merged images (D) in the EPL and GL after SE. Some of the PV-positive interneurons are co-localized with NeuN (arrows). Similar to the PV immunoreactivity pattern, the NeuN expression in the EPL and GL is significantly decreased following SE. All data are presented as mean ± SEM. *P < 0.05, **P < 0.01 vs. control. Glomerular layer; GL, external plexiform layer; EPL, H; hours, M; months. Scale bar = 17 μm.

In the present study, we observed the neuronal degeneration and morphological changes following pilocarpine-induced SE in the rat MOB. Not only PV-positive interneurons but also NeuN-positive neurons were decreased time-dependently after pilocarpine treatment. Several previous studies have reported that SE resulted in oxidative stress and neuroinflammation in the brain subregions, including the hippocampus and olfactory bulb, causing seizure-induced neuronal damage (15, 16). In addition, functional and morphological abnormalities of the olfactory bulb were observed in the temporal lobe of epilepsy patients (7) and the olfactory bulb volumes were decreased in the temporal lobe of epilepsy patients (17). Therefore, because stimulations of the olfactory bulb can also induce seizures in a certain mouse model (18), these phenomena may support a close correlation between olfactory bulb function and epileptogenesis.

The MOB is generally known as a useful region for investigating neuronal interactions due to its distinct structures and diversity of neuroactive substances (19). Excitatory mitral and tufted cells have reciprocal dendrodendritic connections with inhibitory granule cells (20). Mitral cells receive odor input from olfactory sensory neurons and glutamate released from the excited mitral cells induces the GABAergic dendrodendritic reversion of granule cells back into mitral cells (21). In the EPL of the rat MOB, PV is expressed in fast-spiking GABAergic interneurons (9, 13) and mitral cells form a reciprocal connection with these PV-positive cells. Feedback inhibition modulates the output of the mitral cells (14). These structural and functional features enable the fine-tuning of odor processing. In addition, it has been reported that PV has a crucial role in modulating intracellular calcium levels that are important for synaptic plasticity (22). In olfactory reciprocal synapses, the release of fast neurotransmitters is mediated by calcium influx through the N- and P/Q-type calcium channels and the magnitude of the dendrodendritic transmission depends on the level.

DISCUSSION

In the present study, we observed the neuronal degeneration and morphological changes following pilocarpine-induced SE in the rat MOB. Not only PV-positive interneurons but also NeuN-positive neurons were decreased time-dependently after pilocarpine treatment. Several previous studies have reported that SE resulted in oxidative stress and neuroinflammation in the brain subregions, including the hippocampus and olfactory bulb, causing seizure-induced neuronal damage (15, 16). In addition, functional and morphological abnormalities of the olfactory bulb were observed in the temporal lobe of epilepsy patients
PV immunoreactivity in the MOB following SE

**Fig. 4.** Double immunofluorescence staining for PV (A, green), MAP2 (B, red), with DAPI (C), and merged images (D) in the EPL and GL after SE. In the control group, MAP2 expression shows dense dendritic trees (B1 and B4). Three months following SE, however, MAP2 expression is remarkably decreased compared to the early time period (B3 and B6). Relative density for MAP2 in the EPL and GL (E). All data are presented as mean ± SEM. **P < 0.01 vs. control. Glomerular layer; GL, external plexiform layer; EPL, H; hours, M; months. Scale bar = 17 μm.

In the SE model of this study, as the level of PV expression decreased, we predicted that decreased calcium buffering capability and impaired inhibitory postsynaptic potential occurred, which consequently resulted in olfaction dysfunction. PV is also involved in the phosphorylation of protein kinase which has a crucial role in cell signal transduction via modulating Ca²⁺ and Mg²⁺ ions, indicating that PV is involved in a variety of cellular processes (23, 24). This suggests that in the MOB of SE rats, decreases in PV-positive interneurons alter not only GABAergic inhibitory functions but also various calcium-dependent cell signaling. In a previous study of rat olfactory bulbs, Hwang et al. (9) reported that PV-positive interneurons had branched and well-developed processes with varicosities and spines like calbindin-positive interneurons. The well-developed processes of PV-positive interneurons have much denser connections with mitral cells than those between granule cells and mitral cells (14). However, we confirmed that PV immunoreactivity and dendritic density was markedly decreased following SE. Oxidative stress and neuroinflammation induced by SE can result in neuronal loss in the olfactory bulb, which decreased dendritic density in this study. In contrast, some studies have suggested that calcium signals are associated with the growth and branching of dendrites (25). Therefore, we can consider a correlation between decreased dendritic density and the roles of PV. Morphological changes in the dendritic processes are closely related to synaptic plasticity (26, 27) and we observed decreased dendritic density in the MOB of the SE rats. Decreases in the dendritic density of PV-positive interneurons important for odor tuning support a functional loss of olfaction.

In the present study, we confirmed morphologically that PV-positive interneurons were detected in the EPL and GL of the rat MOB and that pilocarpine-induced SE resulted in neurodegeneration and a decrease in PV- and NeuN-positive neurons. In the MOB, the reciprocal interaction of PV-positive interneurons with mitral cells is crucial for odor tuning (14) and the roles of PV for modulating calcium levels are essential for synaptic transmission and various neuronal function. Thus, the SE-induced changes in PV expression in the MOB strongly support the loss of olfaction seen in epilepsy patients.

**MATERIALS AND METHODS**

**Experimental animals**
All experiments utilized the progeny of Sprague-Dawley rats obtained from the Experimental Animal Center, Soonchunhyang University (Cheonan, South Korea). All animals were provided with a commercial diet and water ad libitum under controlled temperature, humidity and lighting conditions (light/dark cycle 12:12, and 22 ± 2°C, 55 ± 5%). All animal protocols were approved by the Administrative Panel on Laboratory Animal Care of Soonchunhyang University (No. SCH16-0051). All possible efforts were made to avoid animal suffering and minimize the number used in the experiments.

**Seizure induction**
The SE rat model was induced by treatment with pilocarpine as previously described (28). The rats were pretreated with lithium-chloride before pilocarpine to ensure a high survival rate. Twenty hours after lithium-chloride (127 mg/kg, i.p.; Sigma-Aldrich, St. Louis, MO, USA) treatment, scopolamine was injected (2 mg/kg, i.p.; Sigma-Aldrich) 30 min prior to pilocarpine (30 mg/kg, i.p.; Sigma-Aldrich) treatment, which induces SE. Two hours following pilocarpine treatment, diazepam was injected for depression. The seizures were classified into 5 grades according to behavioral characteristics (28), and the SE animals used in the study, consistently exhibited 4 or 5-grade seizures until they were injected with diazepam. For the study, the animals were divided into three groups; the control group, and groups at six hours and three months after SE.

**Fluo-ro-jade b (FJB) staining**
To identify degeneration, FJB staining was performed (29). Each section of the MOB was mounted on gelatin-coated slides and air-dried overnight. The slides were immersed in 1% NaOH in 80% alcohol for 5 min, 2 min in 70% alcohol, and 2 min in distilled water. Then, the slides were transferred to a 0.06% potassium permanganate solution for 10 minutes. The slides were washed in distilled water for 2 minutes. The staining
solution was prepared from a 0.01% stock solution of fluorojade b (Millipore, Burlington, MA, USA) in 0.1% acetic acid. The slides were incubated in a final concentration of 0.0004% for 20 min, then dried for 1 hour. After drying, the slides were rinsed 1 min in xylene. The slides were mounted in mounting medium 4′,6-diamidine-2′-phenyldi-indole dihydrochloride (DAPI) (Vector Laboratories, Burlington, CA, USA). All images were captured using a model Fluoview FV10i and FV10i software (Olympus, Japan).

Immunohistochemistry and double immunofluorescence
The anesthetized animals (urethane 1.5 kg/kg, i.p.; Sigma-Aldrich) were perfused transcardially with phosphate-buffered saline (PBS), followed by 4% paraformaldehyde in 0.1M phosphate-buffer (PB) (n = 5 in each group). The brains were removed and post-fixed in the same fixative for 4 h, and rinsed in PBS containing 30% sucrose at 4°C for 2 days. Thereafter, the tissues were frozen and sectioned with a cryostat at 30 μm thickness and consecutive sections were collected in six-well plates containing PBS. The sections were incubated with primary rabbit anti-PV antibody (1:10000, Swant, Switzerland) in PBS containing 0.3% Triton X-100 overnight at room temperature. The sections were washed 3 times for 10 min with PBS, incubated sequentially in biotinylated goat anti-rabbit IgG (1:200, Vector Laboratories) and ABC complex (Vector Laboratories). The sections were visualized with 3,3′-diaminobenzidine (DAB) in 0.1 M Tris buffer and mounted on gelatin-coated slides. The immunoreactions were observed using DMRB microscope (Leica, Germany) and the images were captured using a model DP72 digital camera and DP2-BSW microscope digital camera software (Olympus, Japan). To establish the specificity of the immunostaining, a negative control test was carried out with pre-immune serum instead of the primary antibody. The negative control resulted in the absence of immunoreactivity in any structures. To identify the morphological changes induced by SE in the same MOB tissue, double immunofluorescence staining for PV/NeuN and PV/MAP2 was performed. The MOB tissues were incubated overnight at room temperature in a mixture of rabbit anti-PV IgG (1:5,000, Swant/mouse anti-NeuN IgG (1:50, Millipore) and rabbit anti-PV IgG (1:5,000, Swant/mouse anti-MAP2 IgG (1:300, Millipore). After washing three times for 10 min with PBS, the sections were incubated in a mixture of Cy2- and Cy3-conjugated secondary antisera (1:200, Jackson ImmunoResearch, Baltimore, PA, USA) for 1 h at room temperature. The sections were mounted with DAPI (Vector). All images were captured using a model Fluoview FV10i and FV10i software (Olympus, Japan).

Western blot analyses
To quantify the expression of PV following pilocarpine-induced status epilepticus (SE), the rats (n = 5 per group) were euthanized with urethane (1.5 kg/kg, i.p.; Sigma-Aldrich). The olfactory bulbs were quickly removed and homogenized in a buffer, as previously described (30). The protein-transferred nitrocellulose membranes (Pall Crop, East Hills, NY, USA) were incubated with rabbit anti-PV IgG (1:10,000, Swant Switzerland) and the data were normalized compared to the β-actin levels as described in a previous study (30).

Quantification of data and statistical analysis
The cell counts were performed by two different investigators who were blinded to the classification of the tissues. Each image was normalized by adjusting the black and white range of the image using Adobe Photoshop v. 8.0. Thereafter, 10 areas per rat (250 × 250 μm² for each area) were selected and the intensity measurements were represented as the mean number of a 256-shade gray-scale (using NIH Image 1.59 software). The optical density values were corrected by subtracting the average background noise values obtained from five image inputs. All data obtained from the quantitative measurements were analyzed using an one-way analysis of variance (ANOVA) to determine the statistical significance. Bonferroni’s test was used for post-hoc comparisons. P-values of < 0.01, 0.05, and 0.005 was considered statistically significant (28).
