Keywords: Air quality, Particulate matter, Income inequality, Life expectancy, Social epidemiology

ABSTRACT

Although studies have shown that air pollution can be devastating to population health, little is known about the health implications of the intersection of air pollution and income inequality. We investigate if air pollution is especially detrimental to the health of US state populations characterized by more inequitable distributions of income. In other words, are the populations of states with higher levels of income inequality especially vulnerable to smaller levels of air pollution? We use two-way fixed-effects panel regression techniques to analyze longitudinal data for 49 US states and the District of Columbia (2000–2010) to model state-level life expectancy as a function of fine particulate matter, income inequality, and other state-level factors. We estimate models with interaction terms to formally assess whether the association between fine particulate matter and life expectancy varies by level of state income inequality. Across multiple life expectancy outcomes and additive models, states with higher PM2.5 levels tend to exhibit lower average life expectancy. This general pattern is observed with our specifications for raw and weighted PM2.5 and with adjustments for income share of the top 10%, total population, GDP per capita, median household income, median age, percent college degree or higher, percent black, and percent Hispanic/Latino. We also find that the association between state PM2.5 levels and average life expectancy intensifies in states with higher levels of income inequality. More specifically, PM2.5 levels are more detrimental to population life expectancy in states where a higher percentage of income is concentrated in the top 10% of the state income distribution. We discuss the implications of our results for future research in social epidemiology and environmental justice.

Introduction

Air pollution is devastating for population health. Over the past two decades, studies have shown that various forms of air pollution (e.g., particulate matter, carbon monoxide, and ozone) increase the risk of heart disease, cerebrovascular disease, all-cause mortality across the life course, cause-specific adult mortality linked to respiratory diseases, cardiovascular diseases, malignant neoplasms, and unintentional injuries (Brook et al., 2010; Brunkkreef & Holgate, 2002; Chay & Greenstone, 2003; Clancy, Goodman, Sinclair, & Dockery, 2002; Currie & Neidell, 2005; Currie, Neidell, & Schmieder, 2009; Franklin, Zeka, & Schwartz, 2007; Graff Zivin & Neidell, 2013; Greenstone & Hanna, 2014; Heutel & Ruhm, 2016; Knittel, Miller, & Sanders, 2016; Künzli et al., 2000; Laden, Schwartz, Speizer, & Dockery, 2006; Mikati, Benson, Luben, Sacks, & Richmond-Bryant, 2018; Mustafić et al., 2012; Pope & Dockery, 2006; Wellenius, Schwartz, & Mittleman, 2005). Although studies have shown that air pollution can be devastating to population health, little is known about the health implications of the intersection of air pollution and income inequality. We investigate if air pollution is especially detrimental to the health of US state populations characterized by more inequitable distributions of income. In other words, are the populations of states with higher levels of income inequality especially vulnerable to smaller levels of air pollution? We use two-way fixed-effects panel regression techniques to analyze longitudinal data for 49 US states and the District of Columbia (2000–2010) to model state-level life expectancy as a function of fine particulate matter, income inequality, and other state-level factors. We estimate models with interaction terms to formally assess whether the association between fine particulate matter and life expectancy varies by level of state income inequality. Across multiple life expectancy outcomes and additive models, states with higher PM2.5 levels tend to exhibit lower average life expectancy. This general pattern is observed with our specifications for raw and weighted PM2.5 and with adjustments for income share of the top 10%, total population, GDP per capita, median household income, median age, percent college degree or higher, percent black, and percent Hispanic/Latino. We also find that the association between state PM2.5 levels and average life expectancy intensifies in states with higher levels of income inequality. More specifically, PM2.5 levels are more detrimental to population life expectancy in states where a higher percentage of income is concentrated in the top 10% of the state income distribution. We discuss the implications of our results for future research in social epidemiology and environmental justice.
Income inequality as a moderator of the association between air quality and life expectancy.

Fig. 1. Income inequality as a moderator of the association between air quality and life expectancy.

2008; Curran & Mahutga, 2018; Diez-Roux, Link, & Northridge, 2000; Hill & Jorgenson, 2018; Lynch et al., 2001; Kaplan, Pamuk, Lynch, Cohen, & Balfour, 1996; Kawachi & Kennedy, 1999; Neumayer & Plümper, 2016; Pickett & Wilkinson, 2015; Rambotti, 2015; Wen, Browning, & Cagney, 2003; Wilkinson & Pickett, 2006, 2009), in this study we are less interested in the direct effects of income inequality on health. Instead, we consider whether air pollution is especially detrimental to the health of US states’ populations characterized by the inequitable distribution of income. In other words, are the populations of US states with higher levels of income inequality especially vulnerable to similar levels of air pollution?

Our assessment of the multiplicative impact of income inequality, as illustrated in Fig. 1, is supported by three theoretical principles: Power, Proximity, and Physiology. The Power principle suggests that income inequality could increase the vulnerability of populations to a given level of air pollution due to the undermining of environmental regulations and protections (e.g., public discussions and warnings, working conditions, living standards, and other resources) through the concentration of wealth and political power. Drawing on a political-economic approach initially developed by Boyce (1994, 2007) and Boyce, Klemmer, Tempel, and Willis (1999), Jorgenson, Schor, Knight, and Huang (2016), Jorgenson, Schor, and Huang (2017), and Jorgenson, Dietz, and Kelly (2018) point out that those with higher incomes and wealth are often the owners of polluting firms and energy producing enterprises. To protect these assets, they are more likely to use their economic resources to influence political power and to dominate the policy environment in their favor (Boyce et al., 1999). These arguments are consistent with Neo-Material theory, which suggests that income inequality concentrates wealth and power among elites and weakens broader commitments to the general interests of society. This creates political pressure to cut taxes, deregulate industries (including less environmental regulations), and limit investments in public resources and social services that promote public health, including, for example, education, consumer protections, and health care infrastructure (Clarkwest, 2008; Kaplan et al., 1996; Kawachi & Kennedy, 1999; Lynch, Smith, Kaplan, & House, 2000; Neumayer & Plümper, 2016; Truesdale & Jencks, 2016).

The Proximity principle suggests that income inequality could increase the vulnerability of populations to a given level of air pollution by contributing to the segregation of vulnerable populations in geographic space. Several studies show that income inequality is associated with higher levels of residential segregation by race and class (Cheshire, Monastiriotis, & Sheppard, 2003; Jargowsky, 1996; Lobman & Wilkinson, 2002; Reardon & Bischoff, 2011). Reardon and Bischoff (2011: 1140) explain that “income inequality appears to be responsible for a specific aspect of income segregation—the large scale separation of the affluent from lower-income households and families.” From public health and environmental justice perspectives, segregation contributes to social inequalities in residential proximity to sources of harmful pollution (Ard, 2016; Boyce & Pastor, 2013; Mikati et al., 2018; Mohai & Saha, 2015). For example, a recent study by Mikati et al. (2018) shows that impoverished and non-white communities are disproportionately exposed to particulate matter emitting facilities. Social Capital theory proposes that these concerns may be compounded, given that income inequality generates widespread status competition, which undermines interpersonal trust, social cohesion, cooperation, and, as consequence, collective political efforts to support vulnerable populations (Elgar, 2016; Kawachi, Kennedy, Lochner, & Prothrow-Stith, 1997; Kawachi & Kennedy, 1999; Truesdale & Jencks, 2016).

Finally, the Physiological principle suggests that income inequality could increase the vulnerability of populations to a given level of air pollution by undermining the physiological health of human populations (Charafeddine & Boden, 2008). Psychosocial theory contends that the stress of relative deprivation, from the unequal distribution of income, contributes to negative self-appraisals (e.g., low self-esteem), emotional distress (e.g., anxiety and anger), risky coping behaviors (e.g., heavy alcohol consumption and smoking), and, over time, physiological dysregulation or allostatic load (Kawachi & Kennedy, 1999; Lynch et al., 2000; Truesdale & Jencks, 2016; Wilkinson, 1996, 2005; Wilkinson & Pickett, 2009). More simply, income inequality creates a wide range of chronic social stressors that in turn overwhelm the physiological stress response or allostatic systems of the human body. When stress is acute or short-term, allostatic systems can efficiently manage the physiological consequences of stress. When stress is chronic or long-term, such as under the enduring economic conditions of heightened income inequality, the result is allostatic load. According to McEwen (1998: 171), allostatic load is “the wear and tear that results from chronic overactivity or underactivity of allostatic systems.” A key indicator of allostatic load is lung function (Crimmins, Johnston, Hayward, & Seeman, 2003; McEwen, 2002; Seeman et al., 2004). Stress and related hormones can contribute to the physiological dysregulation of the lungs through bronchodilation and increased respiration (lungs take in more air), airway inflammation and difficulty breathing (lungs take in less air), and suppression of the immune system, which leads to increased vulnerability to respiratory infections (Kullowatz et al., 2008; Lehrer, 2006). These processes are especially relevant for specific forms of air pollution, most notably fine particulate matter, which can be inhaled deeply into the lungs.

In our review of the research literature, we could find only one quantitative study of the health implications of the intersection of air pollution and income inequality. Using data from the 2001 Behavioral Risk Factor Surveillance System, Charafeddine and Boden (2008) found that the association between county-level fine particulate matter and individual-level fair or poor self-rated health was moderated by state-level income inequality, measured as a Gini coefficient. However, the association between fine particulate matter and individual-level self-rated health was most pronounced at low levels of income inequality. The authors concluded that their analyses could be limited by the “subjective nature” of their dependent variable and recommended that future research explore more “objective outcomes” like “mortality or hospitalization.”

Building on the work of Charafeddine and Boden (2008), we use longitudinal statistical modeling techniques to directly assess the multiplicative impact of income inequality on the association between fine particulate matter and life expectancy, a well-established objective measure of population health, at the US state level. In accordance with previous research, which does not consider additional moderating effects, we expect that states with higher levels of fine particulate matter will tend to exhibit lower average life expectancy. Drawing on the theoretical principles of Power, Proximity, and Physiology, we anticipate that the inverse association between particulate matter and average life expectancy will be greater in states with higher levels of income inequality.

Methods

Data

This study involves the analyses of two datasets. The first dataset includes annual observations for average life expectancy at birth from
2000 to 2010 for 49 US states and the District of Columbia (550 total observations). The second dataset is restricted to three annual observations (2000, 2005, and 2010) for sex-specific average life expectancy for 49 US states and the District of Columbia (150 total observations). These specific years were selected to include all available comparable data for our focal independent and dependent variables. Maine is excluded from all analyses due to data limitations for our particulate matter measures. The second dataset is restricted to the three yearly observations five years apart due to data availability limitations for our sex-specific life expectancy measures.

**Measures**

**Life expectancy**

Our analyses include three dependent variables: (1) average life expectancy at birth, (2) average female life expectancy at birth, and (3) average male life expectancy at birth. These data were obtained from the Institute for Health Metrics and Evaluation’s (IHME) Global Burden of Disease database. IHME provides these data for all states and the District of Columbia (see Wang, Schumacher, Levitz, Mokdad, & Murray, 2013).

**Air quality**

Our focal indicator of air quality is particulate matter 2.5 (PM$_{2.5}$). PM$_{2.5}$ refers to fine inhalable chemical particles in the air. Most particulate matter is a combination of chemicals (e.g., sulfur dioxide and nitrogen oxides) emitted from transportation vehicles, power plants, and other industrial sites. Because these chemical particles are 30 times smaller than a single strand of hair, they can contribute to a host of health problems by travelling through the respiratory tract into the lungs and bloodstream. We obtained PM$_{2.5}$ concentration data from Environmental Protection Agency’s Air Quality System (AQS) database. AQS provides, among other measures, annual average arithmetic mean PM$_{2.5}$ concentrations by air quality monitors. Following Heutel and Ruhm (2016), we weighted state average particulate matter concentrations in order to compensate for the uneven distribution of monitors across space and time by the product of the monitor’s county population and the proportion of actual to potential observations. County populations were obtained from the U.S. Census Bureau’s intercensal population estimates. Potential observations were defined as the total number of observations required by Federal law for each monitor. As robustness checks, in the analyses we estimate separate models with the weighted and unweighted versions of PM$_{2.5}$.

**Income inequality**

Following recent research (e.g., Hill & Jorgenson 2018; Jorgenson et al., 2017, 2018), we measure income inequality as income share of the top 10%. We gathered these state-level inequality data from the World Wealth and Income Database (WWID), developed by Mark Frank et al. (http://www.wid.world/#Database). These data are measured in percentages. The inequality measures are constructed from individual tax filing data available from the Internal Revenue Service. For in-depth information on the creation of the state-level income inequality measures, see Frank, Sommeiller, Price, and Saez (2015).

**Control variables**

Consistent with previous studies of air quality and income inequality, our analyses include a range of state-level time-varying control variables, including median age (in years), percent black, percent Hispanic/Latino, percent with a four-year college degree or higher, median household income (in constant 2016 US dollars), GDP per capita (in chained 2007 dollars), and total population size. Our GDP data were obtained from the United States Department of Commerce Bureau of Economic Analysis database. Data for all other control variables were drawn from the U.S. Census Bureau’s online databases. Because several control variables were positively skewed, the subsequent regression analyses employ a base 10 logarithmic transformation for the state-level measures of percent black, percent Hispanic/Latino, percent with a four-year college degree or higher, GDP per capita, and total population.

**Model estimation techniques**

In our analysis of average life expectancy (annual observations for 2000–2010), we use the “xi:xtpsce” commands in Stata to estimate time-series cross-sectional Prais-Winsten regression models with panel-corrected standard errors, allowing for disturbances that are heteroskedastic and contemporaneously correlated across panels (Beck & Katz, 1995). We correct for first-order autocorrelation (AR1 disturbances) within panels. Since we have no theoretical basis for assuming panel-specific autocorrelation, we treat AR1 disturbances as common to all panels. We control for both year-specific and state-specific effects by including dummy variables for years and cases. This approach is one of the most commonly used longitudinal methods because it addresses the problem of heterogeneity bias. Heterogeneity bias in this context refers to the confounding effect of unmeasured time-invariant variables that are omitted from our regression models. To correct for heterogeneity bias, fixed-effects models control for omitted variables that are time-invariant by examining variability within states rather than between states. To control for potential unobserved heterogeneity that is cross-sectionally invariant within periods, we include dummy variables for our annual observations (i.e., period-specific intercepts) with the year 2000 serving as the reference category. The inclusion of period-specific intercepts is equivalent to modeling temporal fixed effects, and including both period-specific intercepts and case-specific fixed effects is analogous to estimating a two-way fixed-effects model (Wooldridge, 2010).

For our analysis of sex-specific average life expectancy (annual observations for 2000, 2005, and 2010), we use the “xtreg” commands in Stata to estimate two-way fixed-effects panel regression models with robust standard errors clustered by state and the District of Columbia. The time fixed effects are accounted for by the inclusion of the year-specific intercepts. With the xtreg suite of commands in Stata, the case-specific fixed effects are estimated using the within estimator, which involves a mean deviation algorithm for the dependent variable and each time-varying independent variable (Allison, 2009).

In our moderation analyses, we calculate and use interaction terms (PM$_{2.5}$ income Share of Top 10%) to formally assess whether the association between air quality and life expectancy varies as a function of income inequality. We also estimate partial slope coefficients for the effect of PM$_{2.5}$ on life expectancy at percentile levels of the moderator variable, income share of the top 10%. These slope coefficients are estimated using the “margins” commands in Stata.

**Results**

**Descriptive analyses**

Table 1 provides univariate descriptive statistics for all substantive variables included in our analyses. Although some variables are converted to logarithmic form for the panel regression analyses, we report descriptive statistics for each variable in their original metrics. The mean for total average life expectancy is nearly 78 years. Average life expectancy is closer to 80 years for females and 75 years for males. Average raw (i.e., unweighted) and weighted air quality estimates indicate moderate levels of PM$_{2.5}$. Our income inequality estimates indicate an average income share of the top 10% of nearly 44%.

**Regression analyses**

Tables 2–4 present the two-way fixed-effects models for total average life expectancy (Table 2), female life expectancy (Table 3), and

male life expectancy (Table 4). The same 8 models are estimated for each dependent variable. Model 1 includes all control variables as well as the raw form of PM2.5, while Model 2 includes the controls and income share of the top 10%. Model 3 includes both raw PM2.5 and income share of the top 10% as well as the controls, while Model 4 also includes the interaction between raw PM2.5 and income share of the top 10%. Models 5–8 are structured the same as Models 1–4, but they instead include the weighted form of PM2.5.

Across all outcomes and relevant additive models (1, 3, 5, and 7), states with higher PM2.5 levels tend to exhibit lower average life expectancy. This general pattern is observed with our specifications for raw and weighted PM2.5 and with adjustments for income share of the top 10%, total population, GDP per capita, median household income, median age in years, percent college degree or higher, percent black, and percent Hispanic/Latino. Since the estimated coefficients are unstandardized, comparing the magnitude of the effects across the independent variables is inappropriate.

To formally assess whether the association between air quality and life expectancy varies as a function of income inequality levels, we tested six interaction terms in Tables 2–4. With the incorporation of the continuous interaction term for PM2.5 * Top 10% Income Share, the linear coefficients for the two variables are to be interpreted as conditional relationships (Jaccard, Wan, & Turrisi, 1990). In other words, the linear coefficient for PM2.5 or for income share of top 10% is the estimated effect on life expectancy when the other variable equals zero, which, like much research across disciplines, does not occur for the analyzed cases. As shown in Table 1, for the analyzed panel data, the minimum value of PM2.5 is 3.60, and for income share of the top 10% the minimum value is 33.56.

Across the three life expectancy outcomes and multiplicative models (4 and 8), the negative association between state PM2.5 levels and average life expectancy intensifies in states with greater income inequality. In other words, PM2.5 levels are more detrimental to population life expectancy in states where a higher percentage of income is concentrated in the top 10%. Table 5 presents partial slopes for the association between PM2.5 and total average life expectancy as a function of income shares to the top 10% (based on the analyses reported in Table 2). At low levels of income inequality (1st and 10th percentiles), PM2.5 is essentially unrelated to average life expectancy. Around the 20th percentile of the income inequality distribution, we begin to see the expected inverse association between PM2.5 and average life expectancy. These partial slopes increase in magnitude through the 99th percentile of the income inequality distribution. Fig. 2 provides a graphic illustration of these patterns. The slope coefficients for the inverse association between PM2.5 and average life expectancy clearly increase in magnitude at higher levels of income inequality, measured as income shares of the top 10%.

In a series of unreported sensitivity analyses, we estimated

in this study, we asked whether air consequences of the intersection of air pollution and income inequality can be devastating to population health, little is known about the health

Discussion

We anticipated that states with higher levels of fine particulate matter would tend to exhibit lower life expectancy. This is what we found. Across all three outcomes and additive models, states with higher PM$_{2.5}$ levels tend to exhibit lower average life expectancy. This general pattern was observed with our specifications for raw and weighted PM$_{2.5}$ and with adjustments for income share of the top 10%, total population, GDP per capita, median household income, median age in years, percent college degree or higher, percent black, and percent Hispanic/Latino. These results are generally consistent with previous research on the population health consequences of air pollution (Brook et al., 2010; Brunekreef & Holgate, 2002; Clay & Greenstone, 2003; Clancy et al., 2002; Currie & Neidell, 2005; Currie et al., 2009; Franklin et al., 2007; Graff Zivin & Neidell, 2013; Greenstone & Hanna, 2014; Heutel & Ruhm, 2016; Knittel et al., 2016; Künzli et al., 2000; Laden et al., 2006; Mikati et al., 2012; Mustafić et al., 2012; Pope & Dockery, 2006; Wellenius et al., 2005).

We also proposed that the inverse association between particulate matter and life expectancy would be intensified in states with greater income inequality. Across our three life expectancy outcomes and multiplicative models, the association between state PM$_{2.5}$ levels and average life expectancy intensified in states with higher levels of

Notes: N = 150. * p < .05, ** p < .01, *** p < .001 (two-tailed). Clustered robust standard errors appear in parentheses. Observations for years 2000, 2005 and 2010 for all US States (except Maine) and the District of Columbia. All models include unreported case-specific fixed effects. All models include state-level controls for Total Population, GDP Per Capita, Median Household Income, Median Age in Years, Percent College Degree or Higher, Percent Black, and Percent Hispanic/Latino.
Generally consistent with the noted principles of Power, Proximity, and Physiology. Past research shows that income inequality undermines the health and functioning of populations (Anderson et al., in press; Clarkwest, 2008; Diez-Roux et al., 2000; Hill & Jorgenson, 2018; Lynch et al., 2001; Kaplan et al., 1996; Kawachi & Kennedy, 1999; Neumayer & Plümper, 2016; Pickett & Wilkinson, 2015; Rambotti, 2015; Wen et al., 2003; Wilkinson & Pickett, 2006, 2009). While we observe an inverse relationship between income inequality and life expectancy, we also provide additional evidence to suggest that income inequality can amplify the health risks associated with environmental degradation.

Our analyses should be considered within the context of multiple limitations. First, our data are limited to only one decade (2000–2010). Second, we examined only one indicator of air quality (fine particulate matter), population health (average life expectancy), and income inequality (income shares to the top 10%). We note that our findings are generally the same if we instead use measures of the income share of the top 5% and the top 1% (see also Hill and Jorgenson, 2018; Jorgenson et al., 2017). Third, income inequality stands in as a black box in our analyses. We offer various theoretical explanations for why income inequality might intensify the effects of particulate matter on life expectancy, but in the present study none of these explanations are assessed empirically. Fourth, we acknowledge that our two-way fixed-effects models likely led to the estimation of relatively conservative coefficients, especially since such models account for multiple forms of heterogeneity bias with the use of case-specific and year-specific intercepts, or the equivalent (Allison, 2009; Treiman, 2009; Wooldridge, 2010). Thus, our results could be viewed as conservative estimates of the effects of particulate matter and income inequality on life expectancy. Fifth, it is possible that our state-level analyses overlook important variation within states, such as at the county level. Finally, our analyses focus explicitly on US states. The extent to which air pollution and income inequality impact population health could be quite different in other Global North nations as well as in nations throughout the Global South. With these limitations in mind, the veracity of our analyses is contingent upon replication using data for subnational units for the US and other nations, with longer study periods and lower levels of aggregation (e.g., county-level analyses), more indicators of air pollution, population health (e.g., infant mortality and cause-specific mortality), and income inequality (e.g., Robin Hood, Atkinson, and Theil), and more direct tests of the theoretical principles of Power, Proximity, and Physiology.

Conclusion

Our findings indicate that fine particulate matter is especially detrimental to life expectancy in US states with higher levels of income inequality. One important implication for social epidemiology is moving beyond the direct and indirect effects of income inequality. Reframing income inequality as an effect modifier, as we have done, opens new doors to the seemingly countless ways in which income inequality can make other established risk factors for population health even worse. Further, a notable implication of our results for environmental justice research is the indexing of environmental inequality according to the broader inequitable conditions of states, in this case income inequality. Thus, a next step includes considering additional moderating effects in relation to racial composition and other sociodemographic characteristics of populations, which could provide a more comprehensive environmental justice analysis. Research along these lines will become increasingly important as broader trends toward neoliberalism continue to drive the deregulation of economic systems, healthcare, and environmental protections (Coburn, 2004; Harvey, 2006).

income inequality. Put differently, PM2.5 levels were more detrimental to population life expectancy in states where a higher percentage of income was concentrated in the top 10% of the state income distribution. To our knowledge, this is the first study to examine the multiplicative impact of income inequality on the association between air quality and life expectancy within the United States.

Our findings make an important contribution to the environmental justice literature, which among other things, emphasizes that uneven levels of exposure to human-caused pollution are tied to forms of structural inequality (Ard, 2016; Boyce & Pastor, 2013; Currie et al., 2009; Devlin et al., 2003; Heutel & Ruhm, 2016; Mikati et al., 2018; Mohai & Saha, 2015). Although not a direct test, our results are also generally consistent with the noted principles of Power, Proximity, and Physiology.
