INTRODUCTION

cl-2 virus (cl-2), isolated from a neuropathogenic murine coronavirus mouse hepatitis virus (MHV) strain, JHM virus (JHM) (1), exhibits extremely high neurovirulence after infection, leading infected mice to morbid states within 3 days post-inoculation (dpi), without inducing demyelination in the white matter of the brain that is observed with other JHMs (2). Instead, it produces necrotic lesions in the grey matter with infected neurons, which do not express the major MHV receptor carcinoembryonic antigen-related cell adhesion molecule 1 (CEACAM1) (3,4). A mutant clone isolated from srr7 (10), and another kind of virus, such as Theiler’s murine encephalomyelitis virus (TMEV) (11). Mechanisms of human brain injuries after infection with human immunodeficiency virus (12), human T-cell leukemia virus I (13), measles virus (14), and influenza virus (15) have also been discussed from the perspective of immune-triggered bystander effects. In the bystander lesions, an antigenic epitope with a Lewis X (Le^a) carbohydrate structure was recently found to be involved in infection with srr7, in mutant mice that lack the gene encoding α1,3-fucosyltransferase 9 (FUT9) (9). FUT9 determines the final structure of Lex (16). However, we failed to clearly detect in vivo Lex expression in the infected organs, including the hippocampus was reported to result from bystander effects of infection with Mu-3, a mutant isolated from srr7 (10), and another kind of virus, such as Thielers’ murine encephalomyelitis virus (TMEV) (11). Mechanisms of human brain injuries after infection with human immunodeficiency virus (12), human T-cell leukemia virus I (13), measles virus (14), and influenza virus (15) have also been discussed from the perspective of immune-triggered bystander effects.

SUMMARY: Although Lewis X (Le^a), a carbohydrate structure, is involved in innate immunity through cell-to-cell and pathogen recognition, its expression has not been observed in mouse monocytes/macrophages (Mo/Mas). The Mo/Mas that infiltrate the meninges after infection with the neuropathogenic murine coronavirus strain srr7 are an initial target of infection. Furthermore, higher inflammatory responses were observed in gene-manipulated mice lacking α1,3-fucosyltransferase 9, which determines the expression of the Le^a structure, than in wild type mice after infection. We investigated Le^a expression using CD11b-positive peritoneal exudate cells (PECs) and found that Le^a is inducible in Mo/Mas after infection with srr7, especially in the syncytial cells during the late phase of infection. The number of syncytial cells was reduced after treatment of the infected PECs with anti-Le^a antibody, during the late phase of infection. In addition, the antibody treatment induced a marked reduction in the number of the infected cells at 24 hours post inoculation, without changing the infected cell numbers during the initial phase of infection. These data indicate that the Le^a structure could play a role in syncytial formation and cell-to-cell infection during the late phase of infection.
**MATERIALS AND METHODS**

**Viruses and Animals:** A neuropathogenic MHV strain, srr7, was used in this study. This virus was propagated and titrated in DBT cells maintained in Dulbecco’s modified Eagle’s minimal essential medium (Gibco, Grand Island, NY, USA) supplemented with 5% heat-inactivated fetal bovine serum (FBS; Sigma, Tokyo, Japan), as previously described (17). Specific pathogen-free inbred BALB/c mice purchased from Charles River (Tokyo, Japan) were housed in a specific pathogen-free animal facility and maintained according to the guidelines set by the ethical committee of our university. For the experiment, mice were transferred to a biosafety level 3 (BSL-3) laboratory, after permission from the committee of our university. Six to seven-week-old mice were used for all experiments.

**Preparation of peritoneal exudate cells:** Thioglycollate medium (TM) was prepared by dissolving 20 g of Brewer thioglycollate (TG) medium (BD Diagnostics, Loveton Circle Sparks, MD, USA), supplemented with 10.0 g of proteose peptone (BD Diagnostics), 2.38 g of sodium chloride (Wako, Osaka, Japan), and 0.945 g of dipotassium phosphate (Wako), in 1,000 ml of distilled water to obtain a TM with components similar to those of the classical product provided by Difco Laboratories (Detroit, MI, USA) (18). TM was autoclaved for 20 min at 15 lbs of pressure at 121°C, and was kept in the dark under sterile conditions at room temperature. Four days after the injection of 2 mL of TM into the peritoneal cavity, the peritoneal cavity was washed with phosphate-buffered saline (PBS; Nissui, Tokyo, Japan), and PECs were collected. To obtain adherent PECs, the cells were seeded at 2 × 10^5 cells per well in 8-well glass-bottom chamber slides (Nalge Nunc International, Rochester, NY, USA), and were cultured in the RPMI 1640 medium (Gibco) supplemented with 10% heat-inactivated FBS (Gibco). After 24 hours, the adherent cells were inoculated with 1.3 × 10^5 or 6.5 × 10^5 plaque-forming units (PFU) of srr7 virus per well and incubated for a specified time. To prepare PECs for flow cytometric analysis, they were cultured in suspension for 24 hours at 2 × 10^7 cells in 1 mL of the medium described above, in 1.5-mL microtubes, with continuous rotation at 20 rpm.

**Assay of adherent PECs:** For immunostaining, adherent PECs were fixed in cold ethanol on chamber slides for 1 min, followed by fixation in cold acetone for 5 min; antibodies and reagents listed in Table 1 were used. Cell cultures labeled with fluorescent dyes were mounted with a gold antifade reagent (Invitrogen, Carlsbad, CA, USA). Fluorescence was visualized under either a confocal laser scanning microscope (Leica Microsystems, Heidelberg, Germany) or a fluorescence microscope (Keyence, Osaka, Japan). The number of infected cells was counted using the BZ analyzer (Keyence). For the inhibition test, either mouse anti-Lewis X mAb (1 : 100) or mouse anti-Sialyl-Lewis X mAb (1 : 100) (Table 1) was added to the culture medium.

**Flow cytometry:** After incubating suspension culture for 24 hours, PECs were inoculated with 1.3 × 10^5 PFU of srr7 virus and were cultured for further 24 hours. Subsequently, the PECs were washed twice in PBS and resuspended in fluorescence-activated cell sorting (FACS) buffer, which contains 1% bovine serum albumin.

Lewis X Expression in Coronaviral Infection

RESULTS

Population and susceptibility of PECs: The PECs that we used were collected after the injection of TM into the peritoneal cavity, and were expected to be mixed populations of leukocytes (19,20). FACS analysis revealed high expressions of CD11b and F4/80 in 50–70% of the PECs (Fig. 1). Around 35% of the PECs were Gr-1-positive (Fig. 1). After viral inoculation, the population appeared grossly similar. However, on double staining for CD11b and Gr-1 (CD11b:Gr-1), a small population (Fig. 1B) showed a relatively high expression of both antigens after infection. Based on F4/80:Gr-1 (Fig. 1B) and F4/80:CD11b (Fig. 1A), similar shifts of the population were observed with the upregulation of Gr-1 and CD11b, respectively, without a significant change in the F4/80 expression level after infection. The PECs attached to the culture glass slides, examined by immunofluorescence staining (IF), also exhibited high expression rates of CD11b and F4/80, in around 70% and 40% of PECs, respectively (Fig. 2A). The population of Gr-1-positive cells among PECs was around 20%. After the inoculation, the population of PECs did not show a marked difference compared to that of culture without viral inoculation (Fig. 2A). Through the inoculation of 2 × 10⁶ PECs with 1.3 × 10³ PFU of srr7, the PECs were found to be susceptible to srr7 infection. The infected area in the culture plate spread rapidly between 12 and 24 hpi (Fig. 1B) forming syncytia (Fig. 3). Some cells with a single nucleus, bearing the Le⁰ antigens without viral antigen expression, were found around the syncytia (Fig. 3C). Unlike CD11b expression in the foot process of PECs, the fine projection was not traceable using anti-Le⁰ antibody (Fig. 4A). However, this does not mean that Le⁰ was not expressed there, because the available antibodies that we used failed to detect Le⁰ expression in monocytes, which bear CEACAM1 that has been proven to be modified by the Le⁰ structure (21), in the normal state (Fig. 3D). Beside CD11b+Le⁰ cells, Gr-1+Le⁰ PECs also appeared as solitary cells with a single nucleus as well as in syncytia with multiple nuclei (Fig. 4B).

FUT9, an enzyme which determines Le⁰ expression (22), showed a similar manner of expression in PECs after infection as Le⁰, i.e. most of the FUT9-positive cells formed syncytia with multiple nuclei (Fig. 4D), which carried CD11b and Gr-1 antigens (Figs. 4C and D). FUT9 antigens were also detected in some solitary cells as well as Le⁰. A noticeable difference between the Le⁰ and FUT9 appearance was observed after kinetic studies. At 12 hpi, Le⁰ was not detectable even in the syncytia (Figs. 4E1 and 2). In contrast, FUT9 antigen was detected at 12 hpi (Figs. 4E3–5). In order to examine whether or not Le⁰ is involved in syncytium formation, we added anti-Le⁰ antibody (anti-Le⁰) to the PEC culture. For the control experiment, we used monoclonal antibody against sialyl-Le⁰ (anti-sialyl-Le⁰), which detects human sialyl-Le⁰, but not that of mice (23), as shown in Fig. 5A. The number of syncytia was decreased when the cultures were treated with anti-Le⁰ during 0–24 hpi, compared to those with anti-sialyl-Le⁰ treatment (Figs. 5A and C). However, the treatment with antibodies did not cause reductions in the cell numbers of the adherent cells (Figs. 5B and E). Furthermore, application of the antibody before infection did not lead to significant differences between treatments with anti-Le⁰ and anti-sialyl-Le⁰ (Figs. 5A and C). The change in the syncytial numbers after treatment with the antibody does not mean a change in the number of infected foci, in other words initial infectivity of the viruses; instead, it means a change in the number of the syncytia that grew large enough to be detectable under a light microscope. Therefore, infected foci during the early phase of infection were counted for viral antigens at 12 hpi using IF, which proved that there were no differences in the numbers of infected cells (Fig. 5D) and the numbers of syncytia (Fig. 5C) at 12 hpi, among cultures with or without these antibodies; corresponding to our previous observation (9) that viral infectivity of PECs derived from Fut9−/− and wild type mice was the same. The treatment with anti-Le⁰ reduced the number of viral antigen-positive cells as well, when counted at 24 hpi (Fig. 5D), which indicated that the antibody inhibits not only syncytium formation but also cell-to-cell infection.

Albumin (BSA; Sigma) and 0.1% NaN3 in PBS. For phenotypic analysis, 1 × 10⁶ cells for each staining were initially incubated with Fc block (BD Biosciences, San Jose, CA, USA) (5 μg/mL) for 20 min at 4°C. Subsequently, the cells were incubated with the appropriate fluorochrome-conjugated antibodies (Table 1) for 30 min at 4°C, followed by 3 washes with FACS buffer, and were acquired on a FACS Calibur (BD Biosciences). Appropriate isotype controls were used in all cases. Data were analyzed using FlowJo software (Tree Star, Jackson, OR, USA).
Fig. 1. (Color online) Flow cytometry of PECs in suspension culture populations of CD11b-, Gr-1-, and F4/80-positive PECs after suspension culture for 24 hours (h) with or without viral infection (Infected [24 hpi] or Uninfected, respectively) were studied by flow cytometric analysis. A): The cells in dotted circle showed a higher expression level of CD11b after infection. B): The cell populations were divided into 4 regions by forward- and side-scatter (FSC and SSC, respectively) profile. The antigen expression patterns of each region (R1-R3) are shown.
DISCUSSION

Although TG-elicited PECs (TG-PECs) were introduced as phagocytes with high purity (24), recent studies using flow cytometry revealed that these TG-PECs have heterogeneous population of leukocytes (19). Even macrophages, identified as CD11b$^+$F4/80$^+$, after gating out B cells, neutrophils, eosinophils, and DCs from the TG-PECs through flow cytometry, appeared heterogeneous, based on the expression of MHC II and Ly6C antigens (20). Various populations of macrophages among TG-PECs have been reported depending upon the gating strategy, including side- or forward-scatter profiles using flow cytometry, or the efficiency of the antibodies used (25). The report of 86–95% macrophages in the TG-PECs (26–28) was criticized as an overestimation by the research group of Misharin (20), who claimed that only 40–45% macrophages and as high as 30–40% eosinophils comprised TG-PECs. Similarly, reports on the population of Gr-1-positive cells in the TG-PECs range from 1% (19) to 40% (20). Our estimated populations of CD11b$^+$, F4/80$^+$, or Gr-1$^+$ cells in the TG-PECs fell into the ranges reported previously. Gr-1$^+$ cells among the TG-PECs were 20–35%.

These PECs, composed of heterogeneous cell populations, were found to be susceptible to Srr7 infection with a similar efficiency compared to DBT cells, which are used for the titration of MHV. It should be noted that most of the synctia formed after infection of TG-PECs expressed Gr-1 antigen. The main target among leukocytes of MHV-JHM infection has been believed to be the lineages of Mo/Mas, including microglia in the brain (5,29), which express CEACAM1. CEACAM1 is also detectable as an adhesion molecule on Gr-1-positive human granulocytes (22). However, it has not been reported that Gr-1-positive cells are the main targets of MHV infection. To determine whether the colocalization of viral and Gr-1 antigens occurred through preferential viral infectivity of Gr-1$^+$ cells, further studies need to be conducted, because Gr-1 antigen might be inducible by endogenous or exogenous factors (30).

Actually, we observed that a small population, with polymorphism among PECs, (Fig. 1B) showed higher Gr-1 expression after infection compared to that detected before infection.

Among these Gr-1-positive cells, Le$^+$ and FUT9 antigen expressions were induced after infection. The antigens were detected predominantly in the infected Gr-1$^+$ and CD11b-positive cells, which formed synctia. The synthesis of Le$^+$ was not involved in the initial formation of synctia, because Le$^+$-positive synctia appeared during the late phase of infection and the inhibition of synctium formation by anti-Le$^+$ was detected during the late phase of infection, but not during the early phase. The Le$^+$ carbohydrate structure does not affect the initial viral infectivity of TG-PECs, because the pre-incubation of TG-PECs with anti-Le$^+$ did not change the number of the infected cells, and the TG-PECs derived from Fut9$^{-/-}$ mice, which do not express Le$^+$ (16), showed the same infectivity as those from wild type mice (9). Therefore, it is indicated that the Le$^+$ structure decorating CEACAM1 has no contribution to the attachment of the virus. A possibility that this structure was involved in the increase in Le$^+$ antigen expression is unlikely, because we did not observe any increase in the CEACAM1 expression after infection, using IF (data not shown). Rather, the expression of the receptor could have been downregulated, like in other kinds of viral infections, including one with human coronavirus (31).

In addition to the roles during development, the Le$^+$ carbohydrate structure, known as stage-specific embryonic antigen-1 (16), is involved in innate immunity through cell-to-cell and pathogen recognition (21,32-34). Dynamic immune regulation is induced after interaction between Le$^+$ carbohydrate structures and lectins serving as C-type lectin receptors (35), which include scavenger receptor with C-type lectin (SRCL), human dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin (DC-SIGN), and its mouse homologue SIGN-related-1 (SIGNR1) (36,37). This CRL-mediated signaling can be turned to a pro-(37) or anti-inflammatory status (38,39) depending on
Fig. 3. (Color online) Antigen expression in the syncytia and solitary cells. Twenty-four hours after seeding PECs on 8-well chamber slides, the cultured cells were infected with $1.3 \times 10^3$ PFU per well, or left uninfected (V$\downarrow$). At 24 hpi, culture slides were processed to detect JHMV (V, A–D), CD11b (A), Gr-1 (B), and Lewis X (Le$^e$, C and D) antigens. Hoechst 33342 (Hoe) was used for nuclear counter-staining, which is shown as a digital blue color (/b). Digital red and green colors are indicated as /r and /g in the pictures, respectively. Note that around syncytia are solitary Gr-1 or CD11b-positive cells not forming syncytia (A and B). Around syncytia, most of the solitary CD11b-positive cells were not infected (narrow arrows in A), whereas all solitary Gr-1-positive cells were infected (narrow arrows in B). Some of these solitary cells around the syncytia projected long foot processes connected with syncytia (bold arrows in A, shown at a higher magnification in A3). At 24 hpi, Le$^e$ antigens were detected in the syncytial cells (C). A few uninfected cells with a single nucleus around syncytia expressed Le$^e$ (narrow arrows in C). In the mock-infected PECs, Le$^e$ antigens were not detected (D). White single and double bars indicate 50 and 25 $\mu$m, respectively.

In spite of these important roles of Le$^e$ carbohydrate structures in immune response, the expression of Le$^e$ has not been detected by IF or flow cytometry in mouse leukocytes, even in monocytes, which express CEACAM1. However, it has been demonstrated, by mass spectrometry, that CEACAM1 carries rich Le$^e$ carbohydrate structures (21). One of the reasons may be that the most sensitive anti-Le$^e$ antibody we examined was of the IgM class, which might be too large to access antigenic sites that are covered by a tertiary conformation of pro-
Lewis X Expression in Coronaviral Infection

We showed that highly expressed Lex was detected in the syncytia and satellite cells (SCs) around the syncytia using Mo/Mas attached to glass slides, which could have been beneficial for the antibodies to reach the antigenic sites in the Mo/Mas, with a fairly well-preserved cell architecture after fixation procedures were employed on the cells attached to the glass slides (41). The connection, through foot processes, between SCs and initial small syncytia might be necessary for them to grow large enough to become detectable with a light microscope, during the late phase of infection, and Lex might be involved in this process. Expression levels detectable by IF during extremely virulent viral infections would provide an opportunity to clarify the functional roles of Lex and its lectins, during infection and immune responses directed not only by mature Mo/Mas but also by dendritic cells, because TG-PECs contain immature CD11b+Gr-1+ cells that can differentiate into dendritic cells (43). Furthermore, among these CD11b+Gr-1+ cells or other carbohydrates. Nevertheless, we showed that highly expressed Lex was detected in the syncytia and satellite cells (SCs) around the syncytia using Mo/Mas attached to glass slides, which could have been beneficial for the antibodies to reach the antigenic sites in the Mo/Mas, with a fairly well-preserved cell architecture after fixation procedures were employed on the cells attached to the glass slides (41). Furthermore, using Mo/Mas attached to glass slides, we could detect that some SCs projected long foot processes connecting to syncytia, mimicking immune synapse, enabling cross-talk between leukocytes several hundred μm apart (42).
Fig. 5. (Color online) Effects of anti-Le^a^ antibody. Anti-Le^a^ (anti-Le^a^) or anti-SLe^a^ (anti-SLe^a^) antibody were added to the PEC culture well before viral inoculation for 1 hour (+) and at the time of inoculation (/), or PECs were cultured without treatment with the antibodies (designated as / or /-, depending on the periods of culture, that is before or after viral inoculation, respectively). Virus was inoculated at an M.O.I of 0.02 (MOI, 0.02) through the experiments except for D-2) to count viral antigen positive cells during the early phase of infection at a higher M.O.I. (MOI, 0.1) A) and B): Immunofluorescent staining for viral antigens (V/g) and SLex (SLex/g) (A), or nuclear staining using Hoechst33342 (Hoe) (B)), with viral infection at 24 hpi (24 hpi) or without (Uninfected). White single bar indicates 50 μm. C), D), and E): Culture slides were processed for immunofluorescent staining for viral antigens (C) and D)) or nuclear staining (E), and photographed using a fluorescent microscope (Keyence). The number of viral antigen-positive cells or nuclei was counted using a BZ analyzer (Keyence). A syncytium was identified when a viral antigen-positive cell had more than 3 nuclei with a major cytoplasmic axis of more than 50 μm. Each experiment was conducted in triplicate, and viral antigen-positive cells or nuclear numbers in each well were counted. p, P-value by Student’s t-test. Asterisks indicate p < 0.05. Vertical lines are the mean ± SD.

 precursor cells, there are myeloid-derived suppressor cells (MDSC) (30), which might expand their population, after extremely virulent viral infection, to contribute to a rapid spread of the viruses. A small population detected by flow cytometry as a shifted population after infection, with elevated expression of CD11b^+ and Gr-1 ^+, may be a candidate for MDSC. The detection of Le^a^ expression in the population is in progress in our laboratory.
