(Dated: July 7, 2015)

Thin films of the ferromagnetic metal SrRuO$_3$ (SRO) show a varying easy magnetization axis depending on the epitaxial strain and undergo a metal-to-insulator transition with decreasing film thickness. We have investigated the magnetic properties of SRO thin films with various thicknesses fabricated on SrTiO$_3$(001) substrates by soft x-ray magnetic circular dichroism (XMCD) at the Ru $M_{4,5}$ edge. Results have shown that, with decreasing film thickness, the film changes from ferromagnetic to non-magnetic around 3 monolayer thickness, consistent with previous magnetization and magneto-optical Kerr effect measurements. The orbital magnetic moment perpendicular to the film was found to be $\sim 0.1 \mu_B$/Ru atom, and remained nearly unchanged with decreasing film thickness while the spin magnetic moment decreases. Mechanism for the formation of the orbital magnetic moment is discussed based on the electronic structure of the compressively strained SRO film.

I. INTRODUCTION

SrRuO$_3$ (SRO), a 4$d$ transition metal oxide with the perovskite-type structure, is a ferromagnetic metal with a relatively high Curie temperature of $T_c \sim 160$ K. The electrical resistivity does not saturate even above 500 K, where the Ioffe-Regel limit is exceeded, indicating highly incoherent nature of the metallic state, i.e., so-called a “bad metallic” behavior. From the device application point of view, SRO is a promising material, e.g., as electrodes because of the chemical stability and the structural compatibility with many functional oxides.

It has been known that the electronic and magnetic properties of epitaxially grown thin films are profoundly affected by the film thickness and the epitaxial strain from the substrates. Several studies have shown that, with decreasing film thickness, SRO thin films exhibit a metal-to-insulator transition and concomitant loss of ferromagnetism at a critical thickness of several monolayer (ML) thickness. Using the laser molecular beam epitaxy (MBE) method, Toyota et al. reported the thickness-dependent electronic structure of SRO films grown on Nb-doped SrTiO$_3$(001) (Nb:STO) substrates by measuring the electrical resistivity and valence-band photoemission spectra. They showed from the temperature dependence of the resistivity that the films changed from metallic to insulating with decreasing thickness. The photoemission spectra of the SRO thin films showed a clear Fermi edge for film thicknesses above 5 ML. With decreasing film thickness, the center of the Ru 4$d$ band moved towards higher binding energies and the intensity at the Fermi level ($E_F$) decreased, resulting in an energy gap opening at the $E_F$ below 4 ML. This indicates that SRO thin film undergoes a metal-insulator transition between 4 ML and 5 ML thicknesses, consistent with the resistivity measurements. The magnetic properties of SRO thin films grown on STO(001) substrates have been investigated by Xia et al. through magnetooptical Kerr effect measurements. With decreasing film thickness, the film showed a transition from ferromagnetic to paramagnetic between 4 ML and 3 ML. Mahadevan et al. performed a density-functional calculation, and found that the SRO film indeed exhibits a thickness-dependent transition from a ferromagnetic metal to an antiferromagnetic insulator at 4 ML. As for the magnetic anisotropy, the magnetic moment was found nearly perpendicular to the film surface. With increasing in-plane lattice constant through increasing the Ba content in (Ba,Sr)TiO$_3$ (BSTO) substrates, the easy magnetization axis changed from out-of-plane to in-plane.

It has been generally considered that perpendicular magnetic anisotropy arises from magneto-crystalline anisotropy caused by spin-orbit interaction. Bruno has shown that the MCA energy is proportional to the difference in the orbital magnetic moment between the perpendicular and in-plane directions, and this has been confirmed for 3$d$ transition metals such as Au/Co/Au(111) thin films and FeCo/Ni multilayers. If the Bruno theory is applicable to Ru compounds, too, the SRO thin films grown on STO are expected to exhibit a finite orbital magnetic moment perpendicular to the plane although the orbital magnetic moment in bulk SRO has been reported to be negligibly small. So far, different values have been reported for the orbital magnetic mo-
ment of Ru in SRO thin films grown on STO substrates not only with (001) surfaces but also with (110) and (111) surfaces\cite{12, 13} and the issue still remains controversial.

The purpose of the present study is to elucidate the thickness-dependent magnetic properties of the SRO thin films grown on STO(001) substrates through the measurements of the spin and orbital magnetic moments using X-ray magnetic circular dichroism (XMCD). We indeed observed a finite orbital magnetic moment of \( \sim 0.1 \mu_B / \text{Ru atom} \) perpendicular to the film surface. The origin of the perpendicular orbital magnetic moment, which should be related to the perpendicular magnetic anisotropy according to Bruno\cite{5}, shall be discussed.

II. EXPERIMENT

SRO thin films were fabricated on TiO\(_2\)-terminated 0.05\% Nb-doped STO(001) substrates by the laser-MBE method with precise control of thickness. The wet-etched STO(001) substrates with TiO\(_2\)-termination were annealed at 1100\(^\circ\)C for 2 hours under an oxygen pressure of \( 1 \times 10^{-7} \) Torr to ensure atomically flat surfaces. Sintered SRO pellets were used as targets. A Nd:YAG (yttrium aluminum garnet) laser was used for ablation in its frequency-tripled mode (\( \lambda = 355 \text{ nm} \)) at a repetition rate of 1 Hz. During the deposition, the substrate temperature was kept at 750\(^\circ\)C and the oxygen pressure at \( 1 \times 10^{-3} \) Torr. The thickness of thin films were determined by reflection high-energy electron-diffraction (RHEED) oscillation. The RHEED pattern showed Kikuchi lines and no three-dimensional Bragg spots, which means that the SRO thin films have flat-ter surfaces and are better crystallized than those fabricated in previous work\cite{14}. Ex situ atomic force microscope studies showed step-and-terrace structures for all the samples. For the samples with 4-8 ML thickness, however, the step edges were irregular, which means that the step-flow growth condition was not achieved\cite{5}. The pseudo-cubic lattice constant of SRO is \( \sim 3.92 \text{ Å} \) and is larger than the lattice constant 3.905 Å of STO by 0.4\%, meaning that the SRO thin films grown on STO substrates are under compressive strain.

Soft x-ray photoemission measurements were performed at the undulator beamline BL-2C of Photon Factory, KEK. X-ray absorption spectroscopy (XAS) and XMCD measurements were performed at the helical undulator beamline BL23SU of SPring-8 except for the sample of 50 ML thickness. As for the sample of 50 ML thickness, XAS and XMCD measurements were performed at the undulator beamline BL-16A of Photon Factory, KEK. For the samples measured at SPring-8, in order to eliminate spurious signals in XMCD spectra, the helicity of the incident circularly polarized light was switched at each photon energy, and two XMCD spectra obtained using opposite magnetic-field directions were averaged. The Ru M\(_{2,3}\)-edge (Ru 3p\( \rightarrow \)4d) XAS and XMCD spectra were taken at 20 K by the total electron yield mode with negative bias. External static magnetic field of 0.1-5 T was applied perpendicular to the film surfaces.

III. RESULT AND DISCUSSION

Magnetization-temperature curves of the SRO films with various thicknesses were measured using a superconducting quantum interference device (SQUID) and are shown in Fig. 1. They show that the magnetization quickly increases above 4 ML, indicating that a paramagnetic-ferromagnetic transition occurs between 3 and 4 ML thicknesses.

Photoemission spectra in the valence-band region are shown in Fig. 2(a). One can see three structures originating from the O 2p band, one of which is located around 4 eV and the others are located around 7 eV and 8 eV\cite{15, 16}. Photoemission within \( \sim 2 \) eV of \( E_F \) is originated from the Ru 4d band\cite{17}. The spectrum for the film thicknesses of 2 ML exhibits an energy gap at \( E_F \), as clearly seen in the spectra near \( E_F \) [Fig. 2(b)]. The leading edge of the Ru 4d band reaches \( E_F \) at 3 ML and the Fermi edge is established at 4 ML, indicating a thickness-dependent insulator-to-metal transition at a critical film thickness between 3 and 4 ML. This critical thickness is the same as that reported in Ref. 5 but by 1 ML smaller than that reported in Refs. 3 and 4.

Figure 3 shows the Ru M\(_{2,3}\) XAS and XMCD spec-
FIG. 2. (Color online) Thickness dependence of the in situ valence-band photoemission spectra of SrRuO₃ thin films grown on Nb-doped SrTiO₃ substrates. (a) The entire valence band, and (b) near the Fermi level region. The Fermi cutoff is clearly seen above 3 ML, indicating the metallic nature of the films.

FIG. 4. (Color online) Thickness dependence of the Ru M₂-edge XMCD spectra of SrRuO₃ thin films. The intensities have been normalized to the Ru M₂-edge XAS intensity.
intensity were measured and are summarized in Fig. 4. According to Fig. 4(a), the XMCD intensity of the 3 ML film show an increase at high magnetic fields, indicating a paramagnetic (or an antiferromagnetic) ground state and a possible metamagnetic behavior. The XMCD intensities of the 4 ML and thicker films, on the other hand, show an abrupt increase from $\mu_B H = 0$ T to almost saturated values at $\mu_B H = 0.1$ T, confirming that these films are ferromagnetic. Figure 4(b) is the thickness dependence of XMCD intensities at several fixed magnetic fields. They all show increase with film thickness above 4 ML at all applied fields.

The thickness and magnetic-field dependences of the orbital and spin magnetic moments have been derived using the XMCD sum rules\(^{17,18}\) and are plotted in Fig. 5. The spin magnetic moment of the thick SRO films is comparable to that of bulk SRO samples\(^{12}\) ($m_{\text{spin}} \simeq 0.6 \mu_B$/Ru). This does not follow the result of first-principles calculation on SRO under epitaxial strain which indicates that the magnetic moment should decrease by $\sim 10\%$ under the compressive strain of 0.4% from the STO substrate\(^{19}\), probably because the accuracy of the previous XMCD measurements on bulk SRO crystals\(^{21}\) was not sufficient to discuss the subtle differences between the bulk and thin film data.

The orbital magnetic moment ($m_{\text{orb}} \simeq 0.08 \mu_B$/Ru) of the thick SRO film is much smaller than 0.2-0.3$\mu_B$ reported in the previous Ru M$_2$ edge XMCD study of SRO films grown on STO(001) and (111) substrates\(^{12}\) but significantly larger than that ($m_{\text{orb}} \simeq 0.0$-0.03$\mu_B$/Ru) reported by the very recent XMCD study at the Ru L$_2,3$ edge XMCD of SRO films grown on STO(001) and (111)\(^{22}\). The discrepancy between the Ru L$_2,3$ edge and the present M$_{2,3}$ edge studies even without overlapping Ti L$_{2,3}$ edges may be due to the large ($\sim 130$ eV) spin-orbit splitting of the Ru L$_{2,3}$ edge which may make the transition-matrix elements for the L$_2$ and L$_3$ edges slightly different. Because the XMCD sum rules have been derived under the assumption that the radial part of the core-level wave functions is the same for the $j = l + 1/2$ and $l - 1/2$ core levels, it may be different if the spin-orbit interaction is very strong. If the L$_2$ edge has a larger (smaller) matrix element than L$_3$, the orbital magnetic moment will be underestimated (overestimated). The reason why the $m_{\text{orb}}$ value reported in Ref. 12 is much larger than ours is not known at present. This discrepancy may be related to the unusually large $m_{\text{spin}}$ value ($\sim 3.4 \mu_B$/Ru) reported in Ref. 12 compared to ours ($\sim 0.6 \mu_B$/Ru) as well as to the value deduced from bulk magnetization measurements ($\sim 1.0 \mu_B$/Ru). As for the 4 ML film, since the spin magnetic moment is smaller ($m_{\text{spin}} \simeq 0.4 \mu_B$/Ru) than that of bulk SRO, the ratio $m_{\text{orb}}/(m_{\text{spin}} + 7m_T)$ is larger in the thin film than in the 50 ML thick film by a factor of $\sim 2$, as plotted in Fig. 5.

The finite orbital magnetic moment perpendicular to the film can be understood from the band structure of SRO as follows: In SRO, the $t_{2g}$ band is partially cupped and spin-polarized while the $e_g$ band is empty. Under the compressive strain, the $t_{2g}$ band is split into the wider $d_{xy}$ band and the narrower doubly degenerate $d_{yz}$/$d_{xz}$ bands. When the spins are perpendicular to the film, i.e., along the $z$ direction, the $d_{yz}$ and $d_{xx}$ bands are mixed through (the $L_z S_z$ term of) the spin-orbit interaction, and the orbital magnetic moment along the $z$ direction is induced. When the spins are parallel to the film, e.g., along the $x$ direction, the $d_{xx}$ and $d_{xy}$ bands are mixed through (the $L_z S_x$ term of) the spin-orbit interaction, and the orbital magnetic moment is induced along the $x$ direction, however, the induced orbital moment is smaller because the wider $d_{xy}$ band is involved. According to Bruno\(^{20}\), the larger orbital magnetic moment perpendicular to the film than that parallel to it should lead to the perpendicular magnetic anisotropy, as confirmed by XMCD for several systems including Co thin films sandwiched by Au(111)\(^{2}\). For the Au/Co/Au(111) film, the orbital magnetic moment parallel to the film increases with decreasing Co film thickness\(^{2}\). In the case of the SRO thin films, the increase of the ratio $m_{\text{orb}}/(m_{\text{spin}} + 7m_T)$ with decreasing film thickness may be induced by a similar mechanism to the Au/Co/Au film. In order to see whether Bruno’s theory\(^{20}\) holds or not for the SRO films, the orbital magnetic moment parallel to the film as well as the orbital magnetic moment of SRO thin films grown on substrates having different lattice constants such as BSTO\(^{24}\) remain to be measured in the future. On the theoretical side, first-principles calculation on SRO thin films explicitly including the Ru 4$d$ spin-orbit coupling ($\sim 150$ meV), which is larger than that of Co 3$d$ ($\sim 70$ meV), is necessary to quantitatively understand the origin of the perpendicular orbital magnetic moment and the perpendicular magnetic anisotropy.
We have performed XMCD measurements on the SRO thin films with various thicknesses grown on STO(001) substrates. With decreasing film thickness, the intensity of the XMCD spectra decreased and the XMCD signal at low magnetic field became very weak below 3 ML, indicating a ferromagnetic-to-paramagnetic transition. While films with thicknesses larger than 4 ML showed strong, magnetic-field-independent XMCD, indicating ferromagnetic behavior, the sample with 3 ML thicknesses showed weak XMCD signals which increases with magnetic field, consistent with (enhanced) paramagnetic behavior. The orbital magnetic moment perpendicular to the film was found to be small but finite (~0.1 $\mu_B$/Ru). The origin of the perpendicular orbital magnetic moment is discussed based on the band structure of SRO under the compressive strain.

If the SRO film is grown under tensile strain (as in the case of Ref. 2), the $t_{2g}$ band is split into the narrower $d_{xy}$ band and the wider $d_{yz}/d_{zx}$ bands, and the magnitude of the orbital magnetic moment would be larger for the in-plane spin direction, for which the narrower $d_{xy}$ band is involved in the spin-orbit coupling.
