Mitigating collinearity in linear regression models using ridge, surrogate and raised estimators

Diarmuid O’Driscoll1 and Donald E. Ramirez2*

Abstract: Collinearity in the design matrix is a frequent problem in linear regression models, for example, with economic or medical data. Previous standard procedures to mitigate the effects of collinearity included ridge regression and surrogate regression. Ridge regression perturbs the moment matrix \( \mathbf{X}'\mathbf{X} \rightarrow \mathbf{X}'\mathbf{X} + k\mathbf{I}_p \), while surrogate regression perturbs the design matrix \( \mathbf{X} \rightarrow \mathbf{X}_s \). More recently, the raise estimators have been introduced, which allow the user to track geometrically the perturbation in the data with \( \mathbf{X} \rightarrow \mathbf{X}_r \). The raise estimators are used to reduce collinearity in linear regression models by raising a column in the experimental data matrix, which may be nearly linear with the other columns, while keeping the basic OLS regression model. We give a brief overview of these three ridge-type estimators and discuss practical ways of choosing the required perturbation parameters for each procedure.

Keywords: collinearity; ridge estimators; surrogate estimators; raise estimators

AMS Subject Classifications: 62J05; 62J07

1. Introduction

The standard linear regression model can be written as \( \mathbf{Y} = \mathbf{X}\beta + \epsilon \) with uncorrelated, zero-mean and homoscedastic errors \( \epsilon \). Here \( \mathbf{X} \) is a full rank \( n \times p \) matrix containing the explanatory variables.
and the response vector \( y \) is \( n \times 1 \) consisting of the observed data. The Ordinary Least Squared OLS estimators \( \hat{\beta}_i \) are solutions of

\[
X'X\hat{\beta} = X'y
\]

given by

\[
\hat{\beta}_i = (X'X)^{-1}X'y.
\]

The solutions \( \hat{\beta}_i \) are unbiased with variance matrix \( V(\hat{\beta}_i) = \sigma^2(X'X)^{-1} \). For convenience, we take \( \sigma^2 = 1 \). The OLS solutions require that \((X'X)^{-1}\) be accurately computed.

### 2. Ridge and surrogate estimators

With economic or medical data, the predictor variables in the columns of \( X \) may have a high level of collinearity; that is, there may be a nearly linear relationship among the predictor variables. In this case, \( X'X \) in Equation (1) is nearly singular and thus \((X'X)^{-1}\) will be numerically difficult to evaluate. It was observed by Riley (1955) that the perturbed matrix \( X'X + kl_p \) with \( k > 0 \) is better conditioned than the matrix \( X'X \) and he suggested using the perturbed matrix in Equation (1). With \( k > 0 \) large enough, \((X'X + kl_p)^{-1}\) can be accurately computed with standard numerical procedures. Using \( X'X \rightarrow X'X + kl_p \) Hoerl (1964) dubbed this procedure ridge regression with ridge estimators

\[
\hat{\beta}_i(k) = (X'X + kl_p)^{-1}X'y.
\]

Near dependency among the columns of \( X \) causes ill-conditioning in \( X'X \) which results in OLS solutions with inflated squared lengths \( ||\hat{\beta}_i||^2 \), with \( \hat{\beta}_i \) of questionable signs (±) and with \( \hat{\beta}_i \) being “very sensitive to small changes in \( X \)” (Belsley, 1986). With ill-conditioning in \( X'X \), the OLS solutions at \( k = 0 \) in Equation (3) are known to be unstable with a slight movement away from \( k = 0 \) giving completely different estimates of the coefficients \( \beta \).

In The International Encyclopedia of Statistical Science, Hadi (2011) discusses two standard remedies for addressing collinearity in linear regression; namely (1) the ridge system \( \{(X'X + kl_p)\beta = X'y; k \geq 0\} \) (Hoerl & Kennard, 1970) with solutions \( \{\hat{\beta}_i(k); k \geq 0\} \) and (2) the surrogate system \( \{(X'X + kl_p)\beta = (X'X\xi_i)\beta = X'\xi_i; k \geq 0\} \) (Jensen & Ramirez, 2008) with solutions \( \{\hat{\beta}_i(k); k \geq 0\} \). The ridge estimators come from modifying \( X'X \rightarrow X'X + kl_p \) on the left side of Equation (1) while the Jensen and Ramirez surrogate estimators modify the design matrix \( X \rightarrow X_k \) on both sides of Equation (1). In matrix notation, ridge regression comes from perturbing the eigenvalues of \( X'X \) as \( \lambda_i \rightarrow \lambda_i + k \), while surrogate regression comes from perturbing the singular values of \( X \) as \( \xi_i \rightarrow \sqrt{\xi_i^2 + k} \). From the singular value decomposition \( X = PDQ' \), the surrogate design is \( X_k = PD(\sqrt{\xi_i^2 + k})Q' \), with \( D \) a diagonal matrix of dimension \( n \times p \), the columns of \( P \) the left-singular vectors and the columns of \( Q \) the right singular vectors. The surrogate transformation \( X \rightarrow X_k \) preserves the ridge moments, with \( X'\xi_iX_k = X'X + kl_p \) allowing for comparison between the two methods. Ridge regression has a long history of use in the statistical literature. The earliest detailed expositions of ridge estimators are found in Marquardt (1963) and Hoerl and Kennard (1970), with Marquardt (1963) acknowledging that Levenberg (1944) had observed that a perturbation of the diagonal improved convergence in steepest descent algorithms. The history of the early use of matrix diagonal increments in statistical problems is given in the article by Piegsch and Casella (1989).

To alleviate the problems inherent with a singular value, say \( \xi_p \) which is indicating collinearity in \( X \), the surrogate transformation converts \( \xi_p \rightarrow \sqrt{\xi_p^2 + k} \) moving the singular value away from zero. Principal Component Regression (PCR) does the opposite and replaces \( \xi_p \) with 0 and regresses \( Y = P\xi_1, \ldots, \xi_{p-1}, 0|x + \epsilon \) with \( \beta = Q\alpha \). Hadi and Ling (1998) have noted “that it is possible for the PCR to fail miserably.” Their example is constructed with the response variable \( Y \) being highly correlated with the deleted eigenvector associated with the deleted singular value. This deletion
results in the remaining explanatory variables being unable to provide a good fit for the response variable.

Since ridge regression is based on a numerical analysis technique, the ridge estimators may lack desirable statistical properties. Three such desirable statistical properties follow.

1. The condition number for a square $p \times p$ matrix $A$ is a measure of the ill-conditioning in $A$ and is defined as the ratio of the largest to smallest eigenvalues, denoted $\kappa(A) \equiv \lambda_{\text{max}} / \lambda_{\text{min}}$. Since perturbation procedures are designed to improve the regression model, one would expect that as $k \to \infty$ that $\kappa(V(\hat{\beta}_k(k))) \to 1$. However, as shown in Jensen and Ramirez (2010a), $\kappa(V(\hat{\beta}_k(k))) \to \kappa(V(\hat{\beta}(0)))$. Initially, as $k$ increases, the ill-conditioning in the variance matrix starts to get better but then returns to the original (bad) value. However, the surrogate system does have the desirable monotone property that $\kappa(V(\hat{\beta}_k(k))) \to 1$ as $k \to \infty$. This allows the user of surrogate estimators to be assured that, regardless of the chosen value for $k$, the variance matrix for the surrogate estimators will be more “orthogonal” than the original OLS variance matrix.

2. Denote $V(\hat{\beta}_k(k)) = \sigma^2(X'X)^{-1} = \sigma^2V$ so $v_{jj}$ is the actual variance for $\hat{\beta}_k(k)$ and denote $X'X = W$. An “ideal” predictor variable in column $j$ would be orthogonal to the other predictor variables in $X$, with $W$ being zero for all off-diagonal values in the $j^{\text{th}}$ row and $j^{\text{th}}$ column. In this “ideal” case, the “ideal” variance for $\hat{\beta}_k(k)$ would be $\sigma^2(W)^{-1} = \sigma^2V^{-1}$, The Variance Inflation Factors (VIFs) of $\hat{\beta}_k(k) = [\hat{\beta}_{k1}, ..., \hat{\beta}_{kp}]'$ are given by $VIF(\hat{\beta}_k(k)) = v_{jj}/\sigma^2$, i.e. the ratios of actual variances to “ideal” variances had the columns of $X$ been orthogonal, with $VIF(\hat{\beta}_k(k)) = 1$ for the ideal orthogonal case. Marquardt and Snee (1975) have identified $VIF$ as “the best single measure of the conditioning of the data.” Again since perturbation procedures are designed to improve the regression model, one would expect that as $k \to \infty$ that $VIF(V(\hat{\beta}_k(k))) \to 1$.

3. Hoerl and Kennard (1970) established that the ridge estimators satisfy the MSE Admissibility Condition assuring an improvement in Mean Squared Error $\text{MSE}(\hat{\beta}_k(k))$ for some $k \in (0, \infty)$. With $\tilde{y}_k(k)$, the predicted values for ridge regression, the statistic $\text{MSE}(\hat{\beta}_k(k)) = \sum (y_j - \tilde{y}_k(k))^2 = ||y - \tilde{y}_k(k)||^2$ measures how close the predicted values in the ridge regression model are to the observed values. However, Jensen and Ramirez (2010b) have shown the existence of cross-over values $k_0$ for which, if $k > k_0$ then $\text{MSE}(\hat{\beta}_k(k)) > \text{MSE}(\hat{\beta}_0(k))$, indicating that the ridge model should not be used. The Hoerl and Kennard (1970) result assures that for some positive value of $k$, the ridge model is an improved model. Jensen and Ramirez (2010a) have shown that for any $k \in (0, \infty)$ the corresponding result holds for surrogate estimators. A further improvement with surrogate estimators is given by $\text{MSE}(\hat{\beta}_k(k)) \leq \text{MSE}(\hat{\beta}_{k_0}(k))$, and $\text{MSE}(\hat{\beta}_k(k)) \leq \text{MSE}(\hat{\beta}_{k_0}(k))$; that is, for any value of $k$, the surrogate estimators have predicted values closer to the original data than the ridge estimators. As the ridge and surrogate estimators are not equivariant under scaling, the common convention is to scale $X'X$ to correlation form with the explanatory variables centered and scaled to unit length.

Remark 1 Scaling $X'X$ to correlation form can lead to some anomalies. As noted in Jensen and Ramirez (2008). For example, the map $k \to ||\hat{\beta}_k(k)||^2$ is known to be monotonically decreasing with $X$ centered but unscaled. Using Proc Reg in SAS with the Ridge option, this monotone property can be lost as the original $X'X$ moment matrix is (1) scaled into correlation form and (2) the ridge estimators are computed using the correlation form for $X'X$ and (3) the ridge solutions are mapped back into the original scale. This scaling-rescaling can cause $k \to ||\hat{\beta}_k(k)||^2$ to lose its monotonicity as in the example in Jensen and Ramirez (2008).
Remark 2  Let $X$ be mean-centered. Let $D_\pi$ be the diagonal matrix with entries $1/X'X_j$, $1 \leq j \leq p$, then the scaling $X \to XD_\pi$ has $(XD)'(XD)$ in correlation form, that is with diagonal entries all having value one. This is the scaling we have used. Sardy (2008) has suggested a covariance-based scaling using the diagonal matrix $D_\pi$ with entries $(X'X_j)^{-1}$, $1 \leq j \leq p$. We note that in this case $(XD_\pi)'(XD_\pi)$ has diagonal entries which are the variance inflation factors $VIF(\hat{\beta}_j)$. The variance inflation factors are the ratios of the variances of $\hat{\beta}_j$ to the “ideal” variances of $\hat{\beta}_j$ assuming the exploratory variables are orthogonal; that is, $VIF(\hat{\beta}_j) = (X'X_j)^{-1}/(1/X'X_j) = (X'X_j)^{-1}X_jX_j = (X'X_j)^{-1/2}XX_jX_j(X'X_j)^{-1/2}$. In our Case Study, $p = 2$ so $VIF(\hat{\beta}_j) = VIF(\hat{\beta}_j)$ and $c(XD)'(XD) = (XD_\pi)'(XD_\pi)$ with $c$ the common value of the variance inflation factors.

Remark 3  When the regression model retains the parameter $\beta_0$ for the constant term with the design matrix $X$ containing a unit constant column, the user needs to be careful with defining $VIF(\hat{\beta}_i)$ when the data have not been mean-centered. In short, $VIF(\hat{\beta}_i)$ is based on comparing the $(i,j)$ entry of the variance matrix to the corresponding entry of an “ideal” covariance matrix. The inverse of the “ideal” covariance matrix is denoted as the “ideal” moment matrix. The “ideal” moment matrix is that (1) the off-diagonal $(i,j)$ and $(j,i)$ entries for cov($\hat{\beta}_i, \hat{\beta}_j$) are zero where $0 < i \neq j$. Note that the “ideal” covariance matrix is not a diagonal matrix as the entries relating to $\hat{\beta}_i$ in the first row and column are retained as the data have not been centered. Additionally, the constraints on the “ideal” moment matrix are that (2) the entries in first row and first column are the first order moments determined from the data and (3) the entries down the diagonal $(i,j)$ with $j \geq 0$ are the second order moments determined from the data. Jensen and Ramirez (2013) have given an easy to compute algorithm for computing the “ideal” covariance matrix that satisfies constraints (1), (2) and (3).

The variance inflation factors, which are the standard measure for collinearity, have a geometric interpretation which allows them to be conveniently computed as a ratio of determinants. We assume that the variables are centered. Reorder $X = [X_{|p|}, X_{|p|}]$ with $X_{|p|} = x_p$ the $p^{th}$ column and $X'_{|p|}$, the design matrix $X$ without the $p^{th}$ column, dubbed the resting columns. Garcia, Garcia and Soto (2011) introduced the metric number to measure the effect of adding the last column $X_{|p|}$ to the resting columns $X'_{|p|}$. An ideal $p^{th}$ column would be orthogonal to the other columns with the entries in the off diagonal elements of the $p^{th}$ row and $p^{th}$ column of $X'X$ all zeros, with idealized $X'X$ moment matrix

$$M_p = \begin{bmatrix} X'_{|p|}X_{|p|} & 0_{p-1} \\ 0_{p-1} & x_p'x_p \end{bmatrix}.$$ 

The metric number is defined by $MN(x_p) = \left(\frac{\det(X'X)}{\det(M_p)}\right)^{1/2}$ and it measures the effect of enlarging the design matrix with the adding of the $p^{th}$ exploratory column. The metric number is easy to compute and is functionally equivalent to the $VIF$ statistics with

$$VIF(\hat{\beta}_p) = \frac{\det(M_p)}{\det(X'X)},$$

for example, O’Driscoll and Ramirez (2015).

In spite of the established usage of ridge regression, it is now known that the surrogate estimators have superior statistical properties over the ridge estimators. Indeed, for their statistical analysis, Woods et al. (2012) used the Jensen-Ramirez surrogate estimates for modelling of diabetes in stock rats.
A crucial question for both the ridge estimators and the surrogate estimators is: What value of \( k \) should be used? McDonald (2009, 2010) has suggested that \( k \) can be determined by controlling the correlation between the observed values and the predicted values from ridge regression. We extend this methodology to surrogate regression and will compare the two procedures.

McDonald (2009, 2010) showed that the square of the correlation coefficient \( R^2(\hat{\beta}_k(k)) \) between the observed values \( y \) and the ridge predicted values \( \hat{y}_k(k) = X\hat{\beta}_k(k) \) is a monotone decreasing function in the ridge parameter \( k \). The corresponding result for the square of the correlation coefficient \( R^2(\bar{\beta}_k(k)) \) of the observed values \( y \) and the surrogate predicted values \( \bar{y}_k(k) = X\bar{\beta}_k(k) \) for the surrogate regression is a monotone decreasing function in the surrogate parameter \( k \), as shown in Garcia and Ramirez (in press). This allows the user to determine a unique value for \( k \) by controlling the decrease in correlation between the observed and predicted values. The user can set a lower bound for the reduction in \( R^2(\hat{\beta}_k(k)) \) and \( R^2(\bar{\beta}_k(k)) \) and numerically compute the associated ridge and surrogate parameters. For example, to preserve 95% of the OLS correlation, we solve \( R^2(k) = 0.95R^2(0) \).

With the computed value for \( k \), we can measure the reduction in collinearity using the VIF statistic or using the condition number \( \kappa \) of \( X'X + kI \). For our case study, we use the example in McDonald (2010) which is known to have severe collinearity. We report the improvements in collinearity for both methods.

### 3. Raise estimators

We assume that the columns of \( X = (x_1, x_2, \ldots, x_p) \) are centered and standardized, that is, \( X'X \) is in correlation form with \( ||x_i||^2 = 1 \). For the \( n \times p \) matrix \( A = [a_1, a_2, \ldots, a_n] \), the column span is denoted by \( Sp(A) \), with \( A_{ij} \) denoting the \( j^\text{th} \) column vector \( a_j \) and \( A_{ij} \) denoting the \( n \times (p-1) \) matrix formed by deleting \( A_{ij} \) from \( A \). For the linear model \( y = X\beta + \epsilon \), central to a study of collinearity is the relationship between \( X_{ij} \) and \( Sp(X_{ij}) \).

The raise estimators are based on perturbing a column \( x_j \) to \( \tilde{x}_j = x_j + \lambda \epsilon_j \) by a \( \lambda_j \) multiple of a vector \( \epsilon_j \) orthogonal to the span of the remaining resting columns. We follow the notation from Garcia and Ramirez (in press). The regression of \( x_j \), viewed as the response vector using the remaining resting columns as the explanatory vectors, has an error vector \( \epsilon_j \) with the required properties. The raise estimators are constructed sequentially as follows.

- **Step 1**: We raise the vector \( x_1 \) from the regression of \( x_1 \) using the resting vectors \( X_{1\setminus j} = \left(x_2, x_3, \ldots, x_p\right) \). From this regression, we take the error vector \( \epsilon_1 \) with \( \epsilon_1 \perp Sp(X_{1\setminus j}) \) to construct \( \tilde{x}_1(\lambda_1) = x_1 + \lambda_1 \epsilon_1 \). The raised design matrix is denoted \( X_{<1>} = \left(\tilde{x}_1(\lambda_1), x_2, \ldots, x_p\right) \).

- **Step j**: we raise the vector \( x_j \) from the regression of \( x_j \) using the resting vectors from \( X_{<j-1>} \), namely \( X_{<j-1\setminus j>} = \left(\tilde{x}_1(\lambda_1), \ldots, \tilde{x}_{j-1}(\lambda_{j-1}), x_{j+1}, \ldots, x_p\right) \). From this regression, we take the residual vector \( \epsilon_j \) with \( \epsilon_j \perp Sp(X_{<j-1\setminus j>}) \) to construct \( \tilde{x}_j(\lambda_j) = x_j + \lambda_j \epsilon_j \). The raised design matrix is denoted \( X_{<j>} = \left(\tilde{x}_1(\lambda_1), \ldots, \tilde{x}_{j-1}(\lambda_{j-1}), \tilde{x}_j(\lambda_j), x_{j+1}, \ldots, x_p\right) \).

- **Step p**: we raise the vector \( x_p \) from the regression of \( x_p \) with the resting vectors from \( X_{<p-1>} \), namely \( X_{<p-1\setminus p>} = \left(\tilde{x}_1(\lambda_1), \ldots, \tilde{x}_{p-1}(\lambda_{p-1})\right) \). Then, we take the residual \( \epsilon_p \) with \( \epsilon_p \perp Sp(X_{<p-1\setminus p>}) \) to construct \( \tilde{x}_p = x_p + \lambda \epsilon_p \). The raised design matrix is denoted \( X_{<p>} \) with parameters vector \( \lambda = (\lambda_1, \ldots, \lambda_p)' \) to be chosen by the user. For convenience, we denote the final raise design \( X_{<p>} \) by \( \bar{X} \).

There is a monotone relationship between the variance inflation factors, \( VIF_j \), and the angle between \( (x_j, Sp(X_{ij})) \), for example, Jensen and Ramirez (2013, Theorem 4). Let \( P = X (X'X)^{-1}X' \) be the projection operator onto the subspace \( Sp(X_{ij}) \subset \mathbb{R}^n \) spanned by the columns of the reduced (or relaxed) matrix \( X \). From the geometry of the right triangle formed by \( (x_j, P X_{ij}) \), it can be shown...
that the angle $\theta_j$ between $x_j$ and $P_{ij} x_{ij}$ satisfies $\cos(\theta_j) = ||P_{ij} x_{ij}||/||x_j||$ and similarly the angle between $\tilde{x}_j$ and $P_{ij} \tilde{x}_{ij}$ satisfies $\cos(\tilde{\theta}_j) = ||P_{ij} \tilde{x}_{ij}||/||\tilde{x}_j||$ since $e_j \perp P_{ij} x_j$. Each Variance Inflation Factor, $VIF_j$ for $\tilde{X}$ is functionally related to the angle $\tilde{\theta}_j$ by the rule $\tilde{\theta}_j = \arccos(\sqrt{1 - 1/VIF_j})$ for example Jensen and Ramirez (2013). Thus as $\lambda_j \to \infty$, $\tilde{\theta}_j \to 90^\circ$ and the variance inflation factor $VIF_j$ converges to one indicating that collinearity is being diminished, as in Garcia et al. (2011, Theorem 4.2).

Some desirable properties of the raised regression method are as follows.

1. Raising a column vector in $X$ does not effect the basic OLS regression model as the raised vector remains in the original $Sp(X)$, $e_j = X_{ij} - P_{ij} X_{ij} \in Sp(X)$ so $Sp(\tilde{X}) = Sp(X)$, as shown in Garcia et al. (2011).

2. Garcia et al. (2011) has shown that the raise estimators satisfy the MSE Admissibility Condition assuring an improvement in Mean Squared Error $MSE(\tilde{\beta}(\lambda))$ for some $\lambda \in (0, \infty)$ and thus the raise estimators can be said to be of ridge-type.

3. The VIFs associated with the raise estimators are monotone functions, decreasing with $\lambda_j$, see Garcia, García, López Martín, and Salmerón (2015).

4. Starting with $XX'$ in correlation form with

$$ XX' = \begin{pmatrix} 1 & \rho_{12} & \rho_{13} & \cdots & \rho_{1p} \\ \rho_{12} & 1 & \rho_{23} & \cdots & \rho_{2p} \\ \rho_{13} & \rho_{23} & 1 & \cdots & \rho_{3p} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \rho_{1p} & \rho_{2p} & \rho_{3p} & \cdots & 1 \end{pmatrix} $$

results in the final raising matrix $\tilde{X}$ having moment matrix

$$ \tilde{X}'\tilde{X} = \begin{pmatrix} 1 + \lambda_1 & \rho_{12} & \rho_{13} & \cdots & \rho_{1p} \\ \rho_{12} & 1 + \lambda_2 & \rho_{23} & \cdots & \rho_{2p} \\ \rho_{13} & \rho_{23} & 1 + \lambda_3 & \cdots & \rho_{3p} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \rho_{1p} & \rho_{2p} & \rho_{3p} & \cdots & 1 + \lambda_p \end{pmatrix} $$

(4)

Thus, the raised regression perturbation matrix is equivalent to a generalized ridge regression perturbation matrix. And conversely, any generalized ridge regression matrix has a corresponding raised regression matrix as in Garcia and Ramirez (in press).

The raise estimators allow the user to specify, for each of the variables, a precision $\pi_j$ that the data will retain during the raising stages by restricting the mean absolute deviation MAD in the $j$th column of $X - \tilde{X}$ from

$$ \lambda_j \frac{1}{n} \sum_{i=1}^{n} |e_{ij}| = \pi_j; $$

(5)

Thus, given a specified precision $\pi_j > 0$, the user can raise column $j$ in $X - \tilde{X}$ to $\tilde{X}(\lambda_j) = x_j + \lambda_j e_j$, where $\lambda_j$ is solved from Equation (5). The precision values should be based on the researcher’s belief in the accuracy of the data. The raised parameters $\lambda_j$ are thus constrained to assure that the original data have not been perturbed more than what the researcher has permitted.
Remark 4 The ridge and surrogate procedures do not require X to be of full rank. For example, with the surrogate transformation \( \xi_i \rightarrow \sqrt{\xi_i^2 + k} \) any zero singular value will be mapped to \( \sqrt{k} > 0 \) with \( X_k \) now full rank. On the other hand, the raise procedure does require the columns of \( X \) to be independent as the crucial step \( x_i \rightarrow x_i(\lambda_i) = x_i + \lambda_i e_i \) moves \( x_i \) in the direction of the orthogonal complement of \( \text{Sp}(X_{11}) \subset \text{Sp}(X) \subset \mathbb{R}^p \) in \( \text{Sp}(X) \), the span of the other columns. Thus if \( x_i \in \text{Sp}(X_{11}) = \text{Sp}(X) \) then \( \text{Sp}(X_{11})^\perp \cap \text{Sp}(X) = \{0\} \) and \( x_i \) cannot be raised.

4. Case study

Our case study is the numerical example in McDonald (2010). Here, \( n = 60 \) and \( p = 2 \) with \( X = [x_1, x_2] \) with \( x_1 \) the nitrogen oxide pollution potential and \( x_2 \) the hydrocarbon pollution potential and \( y \) the total mortality rate in 60 US metropolitan areas. The original data-set had 15 explanatory variables. Following McDonald (2010), we concentrate on the two variables which have the highest correlation \( p = 0.9838 \). Since, \( X \) is assumed to contain only explanatory variables, the vectors \( x_1, x_2 \) and \( y \) are all mean-centered and scaled to have unit length.

Table 1 reports results for OLS, ridge and surrogate regression for the case study. The squared correlation between the original data \( y \) and the predicted values \( \hat{y}(k) \) for OLS is 0.3249. The perturbation parameter for ridge and surrogate are chosen to retain 95% of this value for the squared
correlation between $y$ and $\tilde{y}_a = X_1 \beta_1(k)$ for the ridge parameter and between $y$ and $\tilde{y}_s = X_2 \beta_2(k)$ for the surrogate parameter. Thus, both methods have the same small decrease in $R^2(y, \tilde{y}(k))$ down to 0.3086 shown in Row 1 of Table 1 and with the associated parameters in Row 2 of Table 1. This allows us to compare the improvement in collinearity between the two procedures. The estimated coefficients are shown in Row 3 of Table 1.

Ridge-type procedures are designed to (1) decrease the squared length of the estimated coefficient $\hat{\beta}^T \beta$ which is given in Row 4 of Table 1; (2) decrease the condition number $\kappa(X'X + kI_p)$ of the matrix which needs to be inverted which is given in Row 5 of Table 1; (3) to decrease the variance inflation factors $VIF$ given in Row 6. Since $p = 2$, both $VIF$s have a common value so only one value appears in Row 6. For each of these three criteria, surrogate regression is shown to be a superior procedure achieving a model with smaller collinearity with comparable loss of squared correlation $R^2(y, \tilde{y}(k))$.

The standard method for computing $VIF$ for ridge regression in correlation form follows the procedure suggested by Marquardt (1970), which is to use the values on the main diagonal values of $(X'X + kI_p)^{-1}X'X + kI_p)^{-1}$. Although this is the correct expression for $R = 0$, it has been shown to be in error for $k > 0$ by Garcia et al. (2015) as the Marquardt expression allows inadmissible values less than one. Thus, we have used Equation (22) and (25) in Garcia et al. (2015) to compute the corrected values for $VIF$ for ridge regression.

From Table 1, we see that the mean absolute deviation MAD for $X = \bar{X}$ from the surrogate system is 0.009158. To compute a comparable raise system of estimators, we will set the precision $\lambda = 0.009158$ in Equation (5). The OLS values from Table 1 are shown in Column 1 of Table 2 for comparisons. Using $\lambda = 0.009158$ in Step 1, we solve for $\lambda = 0.5671$ to raise $x_1 \rightarrow \bar{x}_1$. With this value, the squared lengths $\hat{\beta}^T \beta = 8.04, \kappa = 51.19$ and $VIF = 13.29$ all showing an improvement in collinearity. The angle between the two column vectors in the design has improved from 10.31° to 15.92°. The corresponding $R^2(y, \bar{x}(\lambda)) = 0.3169$ indicates that 97.5% for the squared correlation has been retained. For Step 2, we solve for $\lambda_2 = 0.3898$ to raise $x_2 \rightarrow \bar{x}_2$. This is the final raised design $\bar{X} = [\bar{x}_1, \bar{x}_2]$. With these values, the squared lengths $\hat{\beta}^T \beta = 4.15, \kappa = 27.43$ and $VIF = 7.36$ all showing an improvement in collinearity. The angle between the two column vectors in the design has improved to 21.62°. The corresponding $R^2(y, \bar{x}(\lambda)) = 0.3147$ indicates that 96.9% for the squared correlation has been retained. Row 8 records MAD which is 0.009158 by construction.

The values in Column 3 of Table 2 are comparable to the values for the surrogate model from Table 1. However, following Marquardt (1970, p. 610), VIF should be less than 10 and thus, for this example, we would favor the raise estimators as the ridge-type method to be used.
