ABSTRACT
From the radial velocities of the N iv λ4058 and He ii λ4686 emission lines, and the N v λ4604-20 absorption lines, determined in digital spectra, we report the discovery that the X-ray bright emission line star Wack 2134 (= WR 21a) is a spectroscopic binary system with an orbital period of 31.673 ± 0.002 days. With this period, the N iv and He ii emission and N v absorption lines, which originate in the atmosphere of the primary component, define a rather eccentric binary orbit (e=0.64 ± 0.03). The radial velocity variations of the N v absorptions have a lower amplitude than those of the He ii emission. Such a behaviour of the emission line radial velocities could be due to distortions produced by a superimposed absorption component from the companion. High resolution echelle spectra observed during the quadrature phases of the binary show H and He ii absorptions of both components with a radial velocity difference of about 541 km s⁻¹. From this difference, we infer quite high values of the minimum masses, of about 87M⊙ and 53M⊙ for the primary and secondary components, respectively, if the radial velocity variations of the He ii emission represent the true orbit of the primary. No He i absorption lines are observed in our spectra. Thus, the secondary component in the Wack 2134 binary system appears to be an early O type star. From the presence of H, He ii and N v absorptions, and N iv and C iv emissions, in the spectrum of the primary component, it most clearly resembles those of Of/WNLha type stars.

Key words: stars: binaries, spectroscopic – stars: individual (Wack 2134, WR 21a) – stars: early-type

1 INTRODUCTION
The X-ray source 1E 1024.0-5732, detected with EINSTEIN, was identified by Caraveo et al. (1989) with the emission line star 2134 in the Wackerling (1970) catalogue, and suggested to be a binary system composed of an O star with a compact companion. Further X-ray data of this source obtained with ROSAT were analyzed by Mereghetti et al. (1994), who described the optical spectrum to be of Wolf-Rayet type, and proposed that the X-rays could arise in the colliding winds of a WN+OB binary system. Thus, the star was added to the Catalog of Galactic Wolf-Rayet stars (Van der Hucht 2001) as WR 21a. Recent interferometric radio
observations detected a weak non-thermal source at the position of Wack 2134, which was also interpreted as due to a colliding wind region in a WN+OB binary (Benaglia et al. 2005).

However, indications of orbital binary motion had not been found thus far. Here we present a radial velocity study of Wack 2134, showing it to be a binary system with an orbital period of 31.673±0.002 days and a rather high eccentricity, e=0.64±0.03.

2 OBSERVATIONS

We have obtained optical spectroscopy of Wack 2134 between 1994 and 2007 at various observatories. A description of the instrumental configuration of each observation is shown in the Table 1. Resolution was determined by measuring the FWHM of comparison-arc emission lines, and the velocity resolution was calculated at 4686 Å.

The spectra obtained at CASLEO, LCO, ESO, and CTIO were processed with IRAF routines, and those obtained at SAAO with FIGARO supported by Starlink.

We have determined the radial velocities (RVs) of Wack 2134 by fitting Gaussian profiles to the observed lines using the IRAF routine NGAUSSFIT (in the STSDAS package). This routine provides an estimation of errors for each fitted parameter. For example, in the fitting of the He ii λ4686A emission lines, we obtained errors in line position of about 11 km s\(^{-1}\) and 6 km s\(^{-1}\), for the CASLEO and echelle spectra, respectively.

The spectra were first normalized to the continuum and, to standardise the RV measurements in the broad lines, we used the position of the core of the line; this procedure has the advantage of being less dependent on the errors in the definition of the continuum.

We do not have any target in common among the different instruments, which could be used as a comparison star to investigate possible wavelength zero-point differences. The different spectral coverages prevented a suitable characterization of any such differences by means of interstellar lines. However, as will be shown in Section 4, we did not detect any significant shifts within our measurement errors.

3 THE SPECTRUM OF WACK 2134

Figure 1 shows a low-resolution optical spectrum of Wack 2134, obtained at SAAO. Note that C iv emission is present in the spectrum, as well as N iv and He ii. N iii is faint, and N v is observed in absorption. Faint absorption lines of H and He ii are also present. The observed optical spectrum of Wack 2134 resembles that of HD 93162 (≡ WR 25), a WN6ha type star and the second brightest X-ray source in the Carina Nebula (NGC 3372), which has also been recently unveiled as a massive binary system (Gamen et al. 2006). The spectrum of Wack 2134 presents intrinsic H and He ii absorptions (see below), as well as the C iv and N iv emissions with comparable intensities. An effort to classify this star has been made by Reig (1999). He found spectral evidence for a WN+Of classification, i.e. a very broad, high-intensity He ii λ4686 emission line but nitrogen (N v λ4604 and λ4620) and hydrogen absorption lines. However, the FWHM of the He ii λ4686 emission line is narrower than 30 Å and, in the following section, we demonstrate that the observed absorption lines move in phase with it, so they belong to the same star. Thus, we prefer to classify Wack 2134 as O3 f*/WN6ha, i.e. as a massive star in an intermediate evolutionary stage between an O-type and a Wolf-Rayet star similar to those found in the R136 cluster (at the center of the 30 Doradus nebula in the Large Magellanic Cloud), cf. Melnick (1985), Walborn & Blades (1997), Massey & Hunter (1998). Many strong interstellar features are observed in the spectrum, indicating that it is a heavily reddened star.

Spectral lines of the secondary component are observed in our high resolution echelle spectra obtained during both quadratures of the binary system (see below). These lines correspond to absorptions of H and He ii. He i lines are not visible in our spectra. Therefore, the secondary component certainly is an early O-type star, probably as early as O4. The spectral type of the secondary may not be much earlier than this, since we observe single N v absorptions when H and He ii appear clearly double. The radial velocity of the N v absorptions corresponds to the WN component (as is shown below).

4 THE RADIAL VELOCITY ORBIT

In all of our spectra we have determined radial velocities of the spectral features by fitting gaussians to the line profiles. Only the strongest emission line, He ii λ4686, could be measured in all spectrograms. Weaker features were also measured in those spectra with higher S/N. Of these, N v absorptions as well as N iv and C iv emissions show radial velocities which follow the orbital motion of He ii λ4686, and thus originate in the atmosphere of the primary WN component. The radial velocities of the absorption lines of H and He ii show much scatter, and are separated into two components only in our high resolution echelle spectra. The radial-velocity measurements of He ii λ4686 emission, of the mean of N v λ4604-20 absorptions, and of the N iv λ4058 emission are presented in Table 2.

We introduced the He ii emission line radial velocities into a Laffer & Kinmann (1965) period search routine. The radial velocities from our spectra do not show large variations from one night to the next, but considerable variations are present between data obtained during different observing runs, thus suggesting a binary period longer than 10 days. The best period found was 31.67 days, with some aliases, i.e. 40.68, 45.64, 63.34 days. An inspection of the distribution of the radial velocities phased with each of those periods readily indicated that the most suitable is 31.67 days and that the orbit of Wack 2134 is very eccentric.

The period of 31.67 days was then introduced as an initial value into a routine for defining the orbital elements of the binary. To this end we used an improved version of the program originally written by Bertiau & Grobben (1969). Taking into account the different instrumental configurations involved in our dataset but also the spectral S/N, we

2 IRAF is distributed by the National Optical Astronomy Observatories, which are operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.
The very massive X-ray bright binary system WR 2134 (= WR 21a)

decided to weight the spectra such that echelle data were assigned a value of 1 and the lowest resolution spectrum 0.1. Thus, SAO data were weighted with 0.1, CASLEO with 0.4, and CTIO with 0.8. We inspected the individual O−C values derived by the program looking for systematic RV shifts, but in all cases the mean of the O−C (of each dataset) remained below 30 km s⁻¹, which we considered as a conservative internal error. Thus we did not apply any zero-point corrections to the data.

We calculated the orbital elements of Wack 2134 independently with the radial velocities of the He II and N IV emissions and the N V absorptions. We adopted the period determined with the most numerous set of radial velocities from the He II emission also for the orbit of the N V absorptions and N IV λ4058 emission. We obtained eccentric orbital solutions, \( e = 0.64 \pm 0.03 \) for the three datasets. Similar times of periastron and of maximum radial velocity found in each dataset indicate that these lines move together, thus belonging to the same component. A similar conclusion is reached for the C IV emission lines, confirming that C and N lines are formed in the same envelope. The orbital elements for the different datasets of radial velocities are listed in Table 3. Figure 2 illustrates the radial velocity orbits of Wack 2134 as defined by the He II λ4686 and N IV λ4058 emission lines, and the N V absorptions. In this Figure we labeled each instrumental-configuration dataset with a different symbol in order to show that there are not systematic shifts among their RVs.

We note that the radial velocity orbit defined by the He II emission has a higher amplitude when compared with the radial velocity orbit defined by the N V absorptions. The higher amplitude of the radial velocity variations of the He II emission in principle could arise from distortions of the emission line by a superimposed absorption moving in anti-
phase, i.e. a He II absorption originating in the atmosphere of the secondary component. However, our spectra do not show any clear evidence for an absorption line originating in the secondary component. On the other hand, if the secondary component were of earlier spectral type, i.e. an O3 star which also shows N v absorptions in its spectrum, then blending of both components could explain the lower amplitude of the radial velocity variations of these absorption lines. Spectra of higher S/N and resolution are needed to verify these hypotheses.

Our high-resolution echelle spectra obtained during orbital phases close to the quadratures (\( \phi \sim 0.03 \) and 0.05) show double absorption lines of H and He II, most clearly seen in He II \( \lambda 5411 \), as illustrated in Figure 3. Measuring the component of the He II \( \lambda 5411 \) absorption line belonging to the assumed O companion in the echelle spectra taken during quadratures (four spectra obtained during maximum RV but only one presenting minimum RV), we obtained a difference in radial velocities of about 541 km s\(^{-1}\) between quadratures. When we did the same with the absorption lines from the WN component, we obtained a radial-velocity difference of about 352 km s\(^{-1}\), which means an orbital semi-amplitude of 174 km s\(^{-1}\), in good agreement with the N IV and He II emission lines. Assuming that the radial velocity orbit defined by the He II \( \lambda 4686 \) emission represents the orbital motion of the primary (WN) component, and the radial velocities of the He II \( \lambda 5411 \) absorption line (corrected by the difference between the systemic velocities of both components) show the secondary orbital motion, we performed a fit of the orbital solution. The new SB2 orbital solution implies very high minimum masses for the binary components, namely \( 87 \pm 6 \text{M}_\odot \) for the primary WN type component, and \( 53 \pm 4 \text{M}_\odot \) for the O4 type secondary component. This solution is depicted in Figure 4. If the radial velocity orbit of the N V absorptions represents the true orbital motion of the primary, then the minimum masses of the primary and secondary components would be \( 83 \pm 22 \text{M}_\odot \) and \( 47 \pm 14 \text{M}_\odot \), respectively. Similar values were obtained when we used both components of the He II \( \lambda 5411 \) absorption line as representing the orbital motion of each star in the system.

With the high minimum masses found from our radial velocity orbit, we would expect to observe eclipses. Wack 2134 has been monitored in V magnitude by the All Sky Automated Survey (ASAS) (cf. Pojmanski 2001). We have examined the public ASAS data of this star. No obvious variations were found in the V magnitudes when we folded them at the spectroscopic binary period of 31.673 days. However, as Wack 2134 is near the faint magnitude limit of the ASAS survey, the V magnitudes show rather high noise. More accurate photometry is needed to rule out, or confirm, the eclipsing nature of this binary.

### Table 3. Orbital solutions corresponding to the radial velocities of the He II \( \lambda 4686 \) emission line, the mean of the N V \( \lambda 4604-20 \) absorption lines, the N IV \( \lambda 4058 \) emission line, and the C IV \( \lambda 5801 \) emission line in the spectrum of Wack 2134. Symbols have the canonical meanings. The last three correspond to, respectively, the mass function, a standard deviation of the fit (parameter defined by Bertieu & Grobben 1969), and the number of data points involved.

*: Heliocentric Julian Date 2,454,000+

Figure 3. He II \( \lambda 5411 \) absorption lines of both primary (WN) and secondary (O) components in the Wack 2134 binary system observed in our high resolution echelle spectra during the quadrature phases of the orbital motion. We also show (in the middle) a spectrum taken at nearly conjunction when the lines from both components are blended. Note that the radial velocities are more extreme in the O-type star, thus indicating a lower mass. Diffuse interstellar bands (DIB), which are blended with the stellar lines in lower resolution spectra, are also indicated.
5 CONCLUSIONS

From the radial-velocity variations of the He \( \text{II} \) \( \lambda 4686 \) emission line in the spectrum of the WN-type star Wack 2134, we found a most probable period \( P = 31.673 \pm 0.002 \) days, thus revealing Wack 2134 as an eccentric binary system \( (e = 0.64 \pm 0.03) \).

Our higher-resolution spectra taken during quadratures show H and He \( \text{II} \) resolved into two components. We could obtain an orbital solution for the secondary component mea-
