Abstract

Binary toxins are among the most potent bacterial protein toxins performing a cooperative mode of translocation and exhibit fatal enzymatic activities in eukaryotic cells. Anthrax and C2 toxin are the most prominent examples for the AB7/8 type of toxins. The B subunits bind both host cell receptors and the enzymatic A polypeptides to trigger their internalization and translocation into the host cell cytosol. C2 toxin is composed of an actin ADP-ribosyltransferase (C2I) and C2II binding subunits. Anthrax toxin is composed of adenylate cyclase (EF) and MAPKK protease (LF) enzymatic components associated to protective antigen (PA) binding subunit. The binding and translocation components anthrax protective antigen (PA63) and C2II of C2 toxin share a sequence homology of about 35%, suggesting that they might substitute for each other. Here we show by conducting in vitro measurements that PA63 binds C2I and that C2II can bind both EF and LF. Anthrax edema factor (EF) and lethal factor (LF) have higher affinities to bind to channels formed by C2II than C2 toxin’s C2I binds to anthrax protective antigen (PA63). Furthermore, we could demonstrate that PA in high concentration has the ability to transport the enzymatic moiety C2I into target cells, causing actin modification and cell rounding. In contrast, C2II does not show significant capacity to promote cell intoxication by EF and LF. Together, our data unveiled the remarkable flexibility of PA in promoting C2I heterologous polypeptide translocation into cells.

Introduction

Binary toxins of the AB7/8 type are highly potent and specialized bacterial protein toxins and are organized in two different polypeptide chains that are separately secreted in the external media of Gram-positive bacteria [1]. Component A is responsible for the intracellular enzymatic activity of the toxin, whereas heptamers or octamers, of the component B are necessary for receptor-binding and translocation of component A into target cells. Given the close homology of structure of the binding components of these two-component toxins it is of importance to decipher whether each component can functionally substitute for each other to intoxicate cells, that we termed cross-reactivity.

One of the most prominent of this type of toxin is anthrax toxin from Bacillus anthracis [2]. This toxin possesses a binding and translocation component, protective antigen (PA) and two enzymatic subunits, edema factor (EF) and lethal factor (LF). Edema factor (EF) is an 89 kilo Dalton Ca2+- and calmodulin-dependent adenylate cyclase which catalyzes the production of intracellular cAMP and causes severe edema. Lethal factor (LF) is a 90 kilo Dalton Zn2+-binding metalloprotease that cleaves mitogen-activated protein kinase kinases (MAPK-kinases) and thereby interferes with the MAPK cascade, a major signaling pathway, triggered by surface receptors, controlling cell proliferation and survival [3,4,5]. The binding component PA is essential for delivery of both enzymes into the target cells [3,6,7]. It is secreted as an 83 kilo Dalton water-soluble precursor form (PA83) and needs to undergo proteolytic activation by cell-bound furin. After the activation of PA83, the remaining 63 kilo Dalton PA63 forms an oligomeric channel responsible for the binding and translocation of EF and/or LF into the cytosol of target cells [8,9,10,11,12].

Clostridium botulinum, well known for the production of potent neurotoxins, produces various protein toxins, such as the AB type C2 toxin [13,14,15]. The binding component of C2 toxin, C2II (60 kilo Dalton after proteolytic cleavage with trypsin), forms heptamers that insert into biological and artificial membranes at an acidic pH and promotes the translocation of the 45 kilo Dalton
enzymatic component C2I into the cytosol of the target cells upon receptor-mediated endocytosis of the complex [16,17]. C2I acts as an ADP-ribosyltransferase on monomeric G-actin, causing disruption of the actin cytoskeleton [18,19].

The enzymatic components of anthrax and C2 toxin differ significantly in their enzymatic activity and do not show any homology in their primary structures. However, the binding components PA and C2II share a considerable sequence homology of about 35% in two of three domains, indicating that they are closely related in structure and hence also in function [3,8,20,21]. In recent years, many important structural features, particularly concerning PA, have been unveiled, such as the Φ-clamp and the loop network responsible for allocation of the PA monomers [22,23]. Interesting details concerning the possible mode of translocation are known, all favoring an acid-induced disassembly of the enzymatic components to a molten globular state, followed by threading of the N-terminal part of the polypeptide chain through the pore [22,23,24,25]. However, the exact mode of transporting the enzymatic components into the cytosol of target cell is still not fully solved. The first crucial step of the translocation mechanism is the binding of the enzymatic components to the receptor-bound prepore on the cell surface [1]. Previous results of our and other groups evidenced that truncated forms of the enzymatic components as well as full size EF and LF block the pores formed by PA63, and that an N-terminal His6-tag strengthens their affinity [20,26,27]. Binding of the N-terminal ends of EF and LF to PA63 is followed by endocytosis, acidification of the endosomes and finally release of the enzymatic components into the cytosol of target cells, where they exert their fatal effect on the cells of the host [3,8,20,21].

Disruption of the actin cytoskeleton [18,19].

Materials and Methods

Materials

PA, LF and EF genes were PCR-amplified from genomic DNA of Bacillus anthracis strain Sterne (a kind gift of Patrice Boquet, Nice, France) and cloned into the pQE30 (Qiagen) expression plasmids, respectively. The N-terminal His6-tag was removed from His6-EF by incubation with thrombin and from His6-LF with enteropeptidase, respectively. Nicked anthrax PA63 from B. anthracis was obtained from List Biological Laboratories Inc., Campbell, CA. One mg of lyophilized protein was dissolved in 1 ml 5 mM HEPES, 50 mM NaCl, pH 7.5 complemented with 1.25% trehalose. Aliquots were stored at −20°C. Channel formation by PA63 was stable for months under these conditions. C2I and C2II genes were PCR-amplified from genomic DNA of Clostridium botulinum D strain 1873 and cloned into pET22 (Novagen) and pQE30 (Qiagen) expression plasmids. All genes were cloned with BamHI-Sal restriction sites. Recombinant toxins containing His6-tags were expressed in Escherichia coli BL21 (DE3) and purified on a Chelating Sepharose Fast Flow column previously chelated with nickel (Amersham Pharmacia Biotech) as recommended by the manufacturer and described previously [5]. Fractions containing toxin were pooled and dialyzed over night against 250 mM NaCl and 25 mM Tris-HCl, pH 8. Recombinant C2II and C2I proteins used for bilayer measurements were cloned in pGEX-2T vector in E. coli BL21 cells and expressed as glutathione S-transferase (GST) fusion proteins with the glutathione S-transferase-fusion Gene Fusion System from Amersham Pharmacia Biotech [17,18]. The proteins were purified as described previously [18] and incubated with thrombin (3.25 NIH units/ml bead suspension) for cleavage of the GST-tag [31]. C2II was activated with 0.2 μg of trypsin per microgram of protein for 30 min at 37°C [31].

Western Blots

The polyclonal antibodies against the N-terminal part of MEK2 (N20) were purchased from Santa Cruz Biotechnology; monoclonal antibodies against β-actin were obtained from Sigma-Aldrich (clone AC-74). Primary antibodies were visualized using goat anti-rabbit or anti-rabbit horseradish peroxidase-conjugated secondary antibodies (DakoCytomation), followed by chemiluminescence detection ECL (GE Healthcare).

Cell culture

Human umbilical vein endothelial cells (HUVECs, a human primary cell line obtained from PromoCell) were grown in serum-free medium (SFM) supplemented with 20% FBS (Invitrogen), 20 ng/ml basic FGF (Invitrogen), 10 ng/ml EGF (Invitrogen) and 1 μg/ml heparin (Sigma-Aldrich) as described previously [32].

Adenylate cyclase activity

Intracellular concentration of cyclic AMP (cAMP) was determined using the Cyclic AMP Assay (R&D Systems).

ADP-ribosylation

Control cells or intoxicated HUVECs (10⁵ cells/conditions) were homogenized in 0.25 ml cold BS1 buffer (3 mM imidazole, pH 7.4, 250 mM sucrose) supplemented additionally with 1 mM phenylmethylsulfonyl fluoride. Cells were lysed by passing through a 1 ml syringe equipped with a 25G x5/8”-needle (U-100 Insulin, Terumo) 40 times. Nuclei were removed by centrifugation for 10 minutes at 4°C. Protein concentrations of the post-nuclear supernatants were determined using DC protein assay (Bio-Rad). ADP-ribosylation was performed for 90 minutes at 37°C on 5 μg of intoxicated cell lysates, supplemented with 0.3 μCi [³²P]-NAD (800 Ci/mmol) and 1 μg of C2I. Proteins were resolved on 12% SDS-PAGE and in vitro ADP-ribosylated actin was revealed using a phosphorimaging system.

Lipid bilayer experiments

Black lipid bilayer measurements were performed as described previously [33]. The instrumentation consisted of a Teflon chamber with two aqueous compartments connected by a small circular hole. The hole had a surface area of about 0.4 mm². Membranes were formed by painting a 1% solution of diphytanoyl phosphatidylcholine (Avanti Polar Lipids, Alabaster, AL) in n-decane onto the hole. The aqueous salt solutions (Merck, Darmstadt, Germany) were buffered with 10 mM MES to pH 5.9 to pH 6. Control experiments revealed that the pH was stable during the time course of the experiments. The binding
components of the binary toxins were reconstituted into the lipid bilayer membranes by adding concentrated solutions to the aqueous phase to one side (the cis-side) of a black membrane. The temperature was kept at 20°C throughout. Membrane conductance was measured after application of a fixed membrane potential with a pair of silver/silver chloride electrodes inserted into the aqueous solutions on both sides of the membrane. Membrane current was measured using a homemade current-to-voltage converter made with a Burr Brown operational amplifier. The amplified signal was monitored on a storage oscilloscope and recorded on a strip chart recorder.

**Binding experiments**

The binding of EF and LF to the C2II channel and the binding of C2I to the PA63, and to the C2II channel was investigated performing titration experiments similar to those used previously to study the binding of 4-aminoquinolones to the PA63 and C2II channels and LF to the PA63 channel in single- or multi-channel experiments [34,35,36]. The PA63 and C2II channels were reconstituted into lipid bilayers. About 60 minutes after the addition of either activated PA63 or C2II to the cis-side of the membrane, the rate of channel insertion in the membranes was very small. Then concentrated solutions of EF, LF or C2I were added to the cis-side of the membranes while stirring to allow equilibration. The results of the titration experiments, i.e., the blockage of the channels, were analyzed using Langmuir adsorption isotherms (see eqn. [1]) [20,37].

\[ G(c) = G_{\text{max}} \frac{1}{(Kc+1)} \]  

(1)

\[ G(c) \] is the conductance of the channels at a given concentration \( c \) of the enzymatic components and \( G_{\text{max}} \) is their conductance.

---

**Figure 1. Interaction of C2I with PA63 channels.**

A: Titration of PA63 induced membrane conductance with C2I. The membrane was formed from diphytanoyl phosphatidylcholine/n-decane, containing about 5,500 channels. C2I was added at the concentrations shown at the top of the panel. Finally, about 40% of the PA63 channels were blocked. The aqueous phase contained 1 ng/ml activated PA63 protein (added only to the cis-side of the membrane), 150 mM KCl 10 mM MES pH 6. The temperature was 20°C and the applied voltage was 20 mV. Note that C2I only blocks PA63 channels when it is added to the cis-side of the membrane (data not shown). B: Lineweaver-Burke plot of the inhibition of the PA63-induced membrane conductance by C2I. The fit was obtained by linear regression of the data points taken from Figure 1A (r² = 0.996654) and corresponds to a stability constant \( K \) for C2I binding to PA63 of \((3.98 \pm 0.063) \times 10^6 \text{ M}^{-1}\) for C2I binding to PA63 (half saturation constant \( K_s = 251 \text{ nM} \)).

doi:10.1371/journal.pone.0023133.g001
before the start of the titration experiment (at \( c = 0 \)). \( K \) is the
stability constant for binding of the enzymatic components of the
binary toxins to the PA63 or C2II channels. The half saturation
constant \( K \) of binding is given by the inverse stability constant \( 1/ K \).
The percentage of blocked channels is given by:

\[
\% \text{ closed channels} = \frac{100 \cdot K \cdot c}{K \cdot c + 1}
\]

(2)

Statistics
Unpaired, two-sided Student’s t-test was used to analyze
biological data with \( * p < 0.05 \). The statistical software used was
Prism 5.0b. The fit of the data from the titrations experiments with
lipid bilayers was performed using the scientific data graphics
application program Fig.P. For most of the fits of the titration data
with eqn. [2] we obtained \( r^2 > 0.99 \).

Results
Interaction of PA63 with C2I in vitro
The stability constant \( K \) for the binding of C2I to the PA63
channel was measured in multi-channel experiments, performed
as described previously [35]. About 60 minutes after addition of
the protein, the rate of conductance increase had slowed down
considerably. At that time, small amounts of a concentrated
enzyme solution were added to the cis-side of the membrane and
the PA63-induced membrane conductance decreased in a dose-
dependent manner. Figure 1A shows an example for a titration
experiment with an applied voltage of 20 mV in 150 mM KCl in
which increasing concentrations of C2I (arrows) were added to the
cis-side of a membrane containing about 5,500 PA63 channels. The
membrane conductance decreased as a function of the C2I
concentration within a few minutes after addition of C2I (see
figure 1A). The data of Figure 1A and of similar experiments were
analyzed using equation [2] as described previously [35,38]. The
plots of the percentage of closed channels as a function of the
enzyme concentrations were used to calculate the stability
constants \( K \) for binding as it is shown in Figure 1B for the data
of Figure 1A. The fit curve (solid line in Figure 1A) corresponds to
a stability constant \( K \) of \((3.90 \pm 0.063) \times 10^6 \text{ M}^{-1} \) for C2I binding
to PA63 (half saturation constant \( K_S = 251 \text{ nM} \)). The stability
constant \( K \) of the binding of C2I to the PA63 channels was
averaged out of at least five individual experiments resulting in \( K \)
\((5.1 \pm 1.5) \times 10^6 \text{ M}^{-1} \) (half-saturation constant \( K_s = 196 \text{ nM} \)) (see
Table 1). Measurements with artificial bilayer membranes of the
wild-type AB components C2II and C2I revealed a stability
constant \( K \) of \((3.7 \pm 0.4) \times 10^7 \text{ M}^{-1} \) with a half saturation constant
\( K_s = 27.2 \text{ nM} \).

Binding of C2II with EF and LF in vitro
As demonstrated in recent studies, EF and LF of anthrax toxin
are able to block the PA63 pore in artificial bilayer membranes at
nanomolar concentrations [20] and C2II channels can be blocked
by their enzymic counterpart C2I [18]. The possible binding of
EF and LF to the C2II channels was studied using titration
experiments as described above for PA63 and C2I shown in
Figure 1. These measurements allowed the calculation of the
stability constants \( K \) of EF and LF binding to the C2II channels,
resulting in \((7.7 \pm 4.8) \times 10^7 \text{ M}^{-1} \) and \((2.0 \pm 0.3) \times 10^7 \text{ M}^{-1} \),
respectively (see Table 1). The data indicated that EF and LF
have a high affinity for the C2II channels in vitro, as the half

saturation constants \( K_s \) for EF and LF binding to the C2II
channels were 13.0 nM and 49.9 nM, respectively.

PA63 translocates C2I in HUVECs
C2I acts as an ADP-ribosyltransferase targeting cellular G-actin.
Therefore, successful delivery of this enzymatic component into
target cells can be detected by disruption of the cytoskeleton
followed by rounding up of target cells and detachment of target
cells from the extracellular matrix, defined as intoxicated cells [18]
or by direct measurement of the modified G-actin as described in
Materials and Methods. C2I, added to different concentrations of its
native binding component C2II, led to increasing numbers of round
cells after 24 hours of intoxication (data not shown).

Figure 2A shows the direct measurement of cellular ADP-
ribosylated actin (ADPr-actin) in HUVECs after treatment with
different PA-C2I and C2II-C2I combinations. The cells were
intoxicated with different concentrations of binding components
and effectors as indicated. Levels of ADP-ribosylated actin (ADPr-
actin) were determined by in vitro ADP-ribosylation of cell lysates
with C2I and radiolabeled \(^{[32P]}\)-NAD. Under these conditions
ADP-ribosylated actin produced by the intoxication process is no
longer labeled by in vitro ADP-ribosylation. The results clearly
demonstrated that the radioactivity combined with labeled ADPr-
actin decreased for the combinations PA-C2I, when PA was
applied in high concentration, and C2II-C2I suggesting that both
channels were able to transport C2I into HUVECs. Controls did
not reveal any change of the labeling of actin, which means that
neither PA nor C2I alone, respectively, modified intracellular actin
(data not shown).

Similar results were obtained when the number of intoxicated
HUVECs was determined by counting round cells as a result of
C2I activity on actin. Figure 2B shows the efficiency of cell
intoxication under different experimental conditions. HUVECs
were incubated with different combinations of PA-C2I and C2II-
C2I as indicated, and the number of intoxicated cells was directly
assessed. The results shown in Figure 2B revealed that the number
of intoxicated cells was highest for the native combination C2II-
C2I. However, when HUVECs were incubated with C2I and
different quantities of PA, rounding of cells was detected even at

| Toxin combination | \( K \) [M\(^{-1}\)] | \( K_s \) [nM] |
|-------------------|-----------------|----------|
| PA with           |                 |          |
| C2I               | \((0.51 \pm 0.15) \times 10^7\) | 196      |
| EF                | \(1.45 \times 10^7\) | 6.9      |
| LF                | \(36.2 \times 10^7\) | 2.8      |
| C2II with         |                 |          |
| EF                | \((7.7 \pm 4.8) \times 10^7\) | 13.0     |
| LF                | \((2.0 \pm 0.3) \times 10^7\) | 49.9     |
| C2I               | \((3.7 \pm 0.4) \times 10^7\) | 27.2     |

Cross-Reactivity of Anthrax and C2-Toxin

Table 1. Stability constants \( K \) and half saturation constants \( K_s \)
for the cross-reaction of anthrax and C2 toxin.

The results clearly demonstrated that the radioactivity combined with labeled ADPr-
actin decreased for the combinations PA-C2I, when PA was
applied in high concentration, and C2II-C2I suggesting that both
channels were able to transport C2I into HUVECs. Controls did
not reveal any change of the labeling of actin, which means that
neither PA nor C2I alone, respectively, modified intracellular actin
(data not shown).

Similar results were obtained when the number of intoxicated
HUVECs was determined by counting round cells as a result of
C2I activity on actin. Figure 2B shows the efficiency of cell
intoxication under different experimental conditions. HUVECs
were incubated with different combinations of PA-C2I and C2II-
C2I as indicated, and the number of intoxicated cells was directly
assessed. The results shown in Figure 2B revealed that the number
of intoxicated cells was highest for the native combination C2II-
C2I. However, when HUVECs were incubated with C2I and
different quantities of PA, rounding of cells was detected even at

| Toxin combination | \( K \) [M\(^{-1}\)] | \( K_s \) [nM] |
|-------------------|-----------------|----------|
| PA with           |                 |          |
| C2I               | \((0.51 \pm 0.15) \times 10^7\) | 196      |
| EF                | \(1.45 \times 10^7\) | 6.9      |
| LF                | \(36.2 \times 10^7\) | 2.8      |
| C2II with         |                 |          |
| EF                | \((7.7 \pm 4.8) \times 10^7\) | 13.0     |
| LF                | \((2.0 \pm 0.3) \times 10^7\) | 49.9     |
| C2I               | \((3.7 \pm 0.4) \times 10^7\) | 27.2     |
lower probability (Figure 2B). This demonstrated that C2I was transported by PA channels into HUVECs. The results of Figure 2B indicated a dose-dependent process as some combinations failed to induce any significant effect compared to the controls.

Interaction of C2II with LF and EF *in vivo* (cell-based assay)

The enzymatic activity of the lethal factor (LF) of anthrax toxin can be measured by monitoring the cleavage of MAPKK, e.g. with MEK2 amino-terminal antibodies (anti-MEK2) [4]. HUVEC monolayers were intoxicated overnight with different combinations of PA-LF or C2II-LF and the activity of LF was analyzed on cell lysates by anti-MEK2 immunoblotting. Control experiments were performed in the absence of binding components. Whereas the wild-type lethal toxin (PA-LF) did not give any MEK2 signal after blotting, the combination of LF with different quantities of C2II revealed a defined signal of intact MEK2 (Figure 3A). Considering our findings that C2II mediated an efficient translocation of C2I into cells under these conditions (Figure 2A and 2B) we can present evidence that C2II has a dramatically lower capacity to promote translocation of LF into target cells.

Anthrax edema factor (EF) is known to increase cAMP in target cells when applied with its native binding partner PA63 [39]. We next tested whether C2II is able to promote translocation of EF by measure of the intracellular concentration of cAMP after overnight incubation of HUVEC monolayers. The combination of PA with EF led to a significant increase of intracellular cAMP level as a function of PA concentration. In contrast, the application of C2II-EF did not increase cAMP cellular levels significantly (Figure 3B). Even at very high concentration of C2II (30 μg/ml) the cellular cAMP level was approximately similar as the control and considerably below the effect of 0.03 μg/ml PA combined with 1 μg/ml EF. This means that translocation of EF by C2II is at least 1000-fold less efficient than PA when the same concentrations of PA and C2II were compared.

We next verified that addition of EF was able to compete with C2I binding to C2II. The results are summarized in Figure 4. At a concentration of 50 μg/ml EF could significantly block C2II-mediated transport of C2I into HUVECs. These data further

![Figure 2. Specificity of HUVECs intoxication by C2I using PA63 in comparison to C2II. HUVECs (5×10^5 cells/100 mm well) were intoxicated with the indicated concentration of polypeptides during 48 (A) or 24 hours (B). A: Cells were intoxicated as indicated and levels of cellular ADP-ribosylated actin (ADPr-actin) were determined by in vitro ADP-ribosylation of cell lysates with C2I and radiolabeled [32P]-NAD. Under these conditions ADP-ribosylated actin formed during the intoxication process is no longer labeled by in vitro ADP-ribosylation, which is indicated by decrease of radioactivity. Immunoblotting anti-beta-actin was performed in parallel on cell lysates to show actin protein levels engaged in the ADP-ribosylation experiments. ADP-ribosylation signals were normalized to actin immunoblot signals. B: Efficiency of cell intoxication. Cells were intoxicated and the number of round cells was directly assessed by counting floating cells. The columns show mean values of 5 independent counting for the individual conditions ± SEM (ns: non significant; * p<0.05 versus control). ](https://doi.org/10.1371/journal.pone.0023133.g002)
suggest that EF binds to the C2II channel in vivo (cell-based assay). Together, these findings show that C2II does not promote cell intoxication by EF and LF efficiently.

Discussion

In previous studies we already demonstrated that the enzymatic components EF and LF of anthrax toxin bind to their B component protective antigen (PA63) and C2I of C2 toxin binds to its B component C2II in vitro [18,20,34]. PA shares significant sequence homology (35%) with C2II, indicating that the two proteins have similar modes of action. PA63 has been crystallized in its monomeric and heptameric prepore form [8] and a model of the C2II prepore structure has been constructed based on the corresponding assembly of the protective antigen prepore [21]. The similarity of both structures supports the view of a common mode of action, including the assumption that the enzymes bind in the vestibule of the channels of the corresponding binding component.

The results presented here suggest an interesting cross-over reactivity of anthrax and C2 toxins, despite a completely different primary and 3D-structure of the enzymatic compounds EF, LF and C2I [40,41,42]. The stability constants $K$ for binding in the cross-over experiments in vitro were generally smaller than those for the native combinations, except the combination of C2II-EF. However, EF, LF and C2I show a high stability constant $K$ for binding to PA63 and C2II heptamers in the cross-over experiments as the half saturation constants $K_s$ are between 2 and about 200 nM (see Table 1). These results refer to a common mechanisms and binding motifs within the enzymes’ primary structures, in particular within the first three hundred amino acids of EF, LF and C2I. Truncated forms of EF and LF, called EFN and LFN, bind with high affinity to the PA63 channels and support the transport of other polypeptides into target cells [26,30,43,44], although the binding affinity of EFN and LFN for the PA63 channel is substantially reduced as compared to wild-type EF and LF [45]. Similarly, the N-terminal part of C2I is sufficient for transport of truncated forms of C2I and chimera proteins between the N-terminal end of C2I and other proteins into target cells [46,47]. This means that the N-terminal ends of all enzymatic compounds interact with the PA63 and the C2II pores. Some of the amino acids responsible for these interactions are well known within the primary sequence of PA63 and its water-soluble prepore, e.g. amino acids E398, D425 and F427 [also known as the $\Phi$-clamp] [22,48,49], but relatively unknown for C2II, although there exist some indications that the corresponding amino acids E399, D426...
conductance as compared to anions [54,55]. It may be possible that binding to the different channels follows different mechanisms. Altogether there exist strong indications that binding to the different channels follows different mechanisms.

Another conceivable possibility is that the structure of the channel itself is important for translocation. The extended channel-forming β-sheets of the PA63 monomers contain three glutamic acids and three aspartic acids (E302, E308, E343 and D276, D315, D335), so the extended β-barrel could contain up to 48 negatively charged groups, which probably cannot be counterbalanced by the at least partially positively charged histidines H304 and H310 [56,57,58]. However, the C2II channel contains 7 glutamic acids (E307) and 14 histidines (H296 and H332), indicating that it has a much smaller overall charge [31]. The interaction of the charged groups of the channel interior and the bound enzymatic components could be different for channels leading to divergent uptake efficiency. Considering the fact that the charges in the vestibule domain are quite balanced in both PA63 and C2II, i.e. both have 14 acidic amino acids facing the interior of the vestibule domain; the effect of the charges in the water filled β-barrels should be striking. As mentioned beforehand, the C2II channel is missing most of them.

The most interesting result of this study was that the combination of PA with C2I showed HUVEC toxicity. This appeared specific of PA considering the rather poor capacity of C2I to bind and to trigger cell intoxication by LF. This clearly reveals that PA has the remarkable ability to bind and to translocate an enzymatic component of another AB$_{1/2}$ type toxin into cells. The level of cell intoxication with C2I via PA, however, was at least 50-fold less efficient than with the wild-type combination C2II-C2I. We can only speculate about the reasons of this higher flexibility of PA as compared to C2I. One possibility is that a different driving force is required to translocate EF and LF through the C2II channel because EF and LF are released at the state of the late endosome [9], whereas C2I leaves the early endosome following acidification and, in addition, depends on the help of the cytosolic chaperon Hsp90 [16,59]. A similar requirement is not known for the translocation of LF, EF or LF’s N-terminal domain (LFN) through the PA$_{63}$ channel, where a pH-gradient across the membrane creates a sufficient driving force for translocation of the proteins [24]. With the evidence presented here, i.e. that some components of the highly specialized binary toxins can be interchanged without loss of toxicity, further work with mutated binding components, enzymatic moieties and chimeras seems to be necessary to understand the different translocation capacities of PA$_{63}$ and C2II channels.
