Introduction

Hearing loss or hearing impairment is one of the most common congenital disorders, with an estimated prevalence of 0.5 to 5 infants per 1000 births [1-4]. The ability to hear during the early years of life is critical for the development of speech, language, and cognition; so even a mild and unilateral hearing loss in children can result in poor language, poor educational outcomes or even lead to a child being incorrectly labeled as having a behavior problem [5,6]. The only way to identify children with hearing impairment at such early time is by neonatal hearing screening. In the beginning of the program implementation period, only infants considered high-risk register (HRR) were contemplated. But it was not enough, given that as many as 50% of infants born with hearing loss have no known risk factors [7].

So today, a universal screening program is being implemented in all neonates. In Portugal, the first recommendations were done in 2005, by a multidisciplinary group named GRISI (Grupo de Rastreio e Intervenção da Surdez Infantil) [8], taking into account the principles and guidelines for interventional program issued by the Joint Committee on Infant Hearing (JCIH) [9]. All screening programs should rely on three mainstays: that all infants should have their hearing screening before their first month of age; for infants who do not pass the screening, diagnostic audiological evaluation should occur before 3 months of age; and infants with a confirmed hearing loss should be enrolled in an early intervention program before 6 months of age, to facilitate age appropriate development of language and social skills. The aim of this study was to determine the outcomes of the hearing screening program in our hospital and to characterize the association between the risk factors and hearing impairment, as well as to determine the prevalence of hearing loss in the group of children without risk factors.

Materials and Methods

It is a retrospective study, conducted in the Department of Otolaryngology and Head and Neck Surgery from a tertiary Hospital Center, during a 5-year-period (from September 2012 till January 2017). The data obtained from each child was maintained...
in two to six register (main register and follow-up registers). The data was analyzed accordingly to identify the most prevalent cause for the hearing loss among these infants. In this period, a total of 10,464 children were born in our hospital, which covers the geographic area of the county of Vila Nova de Gaia. All the infants born in the mentioned period were submitted to hearing screening tests. The selected population for the study included the newborns referred to ENT Department of our hospital, that is, who initially passed the hearing screening tests but were identified to have one or more risk factors for hearing loss and those who failed the initial hearing screening tests. Data were extracted regarding newborn hearing screening from a database in our department and from the records in children’s clinical files.

According to the screening protocol, all newborns were screened in the maternity center during the first 48 hours of life using transient evoked optoacoustic emissions (TEOAEs). “Pass” means ear passed the test and “Refer” means ear failed the test. “Refer” result requires another evaluation at the maternity center, generally during the second week of life. Then a persistent “Refer” outcome requires referral for further evaluation in the Otolaryngology Department of our hospital center. That means that we evaluated all the newborns who had a persistent “Refer” outcome and all those who had at least one risk factor for hearing loss, regardless of the neonatal screening outcome. A complete otolaryngologic evaluation was performed in every referred neonate, as well as auditory brainstem response audiometry (ABR). Whenever necessary, a CT (computed tomography)-scan was performed, usually to characterize anatomic anomalies of the middle ear in syndromic children. Sensorineural hearing impairment was considered when ABR results showed high electrophysiological threshold (above 40dB).

The analyzed risk factors were the following: premature birth (<37 weeks), very low birth weight (<1500g), low Apgar score (0-4 at 1 min and 0-6 at 5 min), exposure to potentially ototoxic medications, severe hyperbilirubinemia that required exchange transfusion, prolonged assisted ventilation (≥5 days), craniofacial anomalies, family history indicating hearing loss, postnatal infection, in utero infection (TORCH), and stigmata or diagnosed syndrome associated with hearing loss. The statistical analysis was performed using SPSS statistics version 25.0. A significance level of 0.05 was applied.

Results
A total of 600 infants were examined. Among these, 53.3% were males and 46.7% were females. The mean gestational age was of 36±3.2 weeks and the mean birth weight was 3200±431.2g.

Hearing Impairment
Within a total 10,464 born neonates, the prevalence of hearing impairment in the referred population was 3.4 per 1000 births, with almost 94% being normal hearers. No significant association was verified between the gender of the neonates and the prevalence of hearing loss. About 89% (n=533) of the newborns had at least one risk factor, while only 11% (n=67) had no risk factors for hearing loss.

Neonates with Risk Factors
The most frequent risk factor was the use of ototoxic medications (n=243; 45.6%), followed by preterm birth (n=155; 29.1%); familial hearing loss (n=148; 27.8%), very low birth weight (n=114; 21.4%); and low Apgar scores (n=67; 12.6%) (Figure 1). The most common concomitant risk factors were preterm birth, very low birth weight and the use of ototoxic medications, verified in 143 children in the risk factor group. The most common potentially ototoxic drug was gentamicin. In this group of children, hearing impairment was verified in 2.43% (n=13). We verified an association between craniofacial anomalies and later development of conductive type of hearing loss (predominantly caused by effusion otitis), in most cases resolved with trans tympanic ventilation tube. This was one of the strongest associations found in our population (p=0.08). Cleft palate was the most common found isolated craniofacial anomaly.

Figure 1: Prevalence of risk factors for hearing loss in the studied newborn population.
Neonates without Risk Factor

A total of 67 children without risk factors for hearing loss that did not pass the initial hearing screening tests were referred to our department for further evaluation. In this group, it was verified a total of 34.3% (n=23) of newborns with hearing impairment; 65.7% (n=44) of the referred neonates without risk factors did not show any degree of hearing loss.

Discussion

The total prevalence of hearing loss in this study was 3.4 infants per 1000 newborns, a value in accordance with the general estimated values described in the literature [1,3,4]. In our population, the most frequent risk factor was the use of ototoxic medications. Ototoxic drugs, specifically aminoglycosides, can be administered to newborns. Preterm birth is a known risk factor for neonatal early-Onset sepsis, mostly caused by group-B Streptococcus and Escherichia coli [10]. The most recommended therapy for the infections caused by these microorganisms is the association between a beta-lactamic and an aminoglycoside (generally Gentamicin) [10-12]. The potential ototoxicity of aminoglycosides may be one of the reasons that justify the rate of hearing impairment in our preterm newborn population.

However, the association between aminoglycoside administration and hearing loss is inconsistent among studies; most studies reported no significant association with treatment duration, total dose, peak or even serum concentrations [13-15], whereas others reported a significant and evidence-based ototoxicity of aminoglycosides [13,14,16,17], particularly on high frequency hearing [17-20]. In some individuals, genetic predisposition is associated with aminoglycoside-induced sensorineural hearing loss, making them particularly vulnerable to this drug toxicity [21]. Other potentially ototoxic drugs described in the literature are loop diuretics; the association between loop diuretics administered to neonates and hearing loss is also inconsistent. However, their use or overuse in combination with other treatments (e.g., aminoglycosides) appears to be associated with sensorineural hearing loss [17,21-23] which needs further investigation.

Other frequent risk factors included specific conditions of the neonate, as gestational age <37 weeks, birth weight <1500g and Apgar score of 0-4 at 1min and/or 0-6 at 5min. Studies analyzing low birth weight used different classifications of birth weight, such as low, very low, or extremely low birth weight. Most studies do not provide evidence of a direct association between the neonatal hearing loss and low birth weight, although the prevalence of sensorineural hearing loss is higher in low birth-weight neonates [24,25]. This can be explained by the factors commonly related to low birth weight that may have impacted hearing, such as assisted ventilation, ototoxic drug administration, or hyperbilirubinemia [18,26].

Most studies failed to account for these confounding variables in multivariable analysis. Therefore, this association is still not completely clarified. Another specific indicator of neonates is the Apgar score, which is used as an indicator of birth asphyxia. Studies analyzing the association between Apgar score with hearing loss were difficult to compare; the timing of the Apgar score and cutoff for birth asphyxia varied considerably. In some studies, a low Apgar score was associated with sensorineural hearing loss or abnormal hearing results, while in others this association was not verified [19,20,27]. Therefore, further studies are required to clarify the duration of asphyxia, permanent characteristics of hearing deficits related to the Apgar score and birth asphyxia, and role of prematurity, which appears to be a confounding factor [19,20,27,28].

We verified that 65.7% of the referred neonates without risk factors for hearing loss did not show any degree of hearing loss in the following auditory assessment tests; this means that there is a high rate of false-positive results concerning the initial automatic Oto mission screening tests performed in the maternity center [29-33]. The hypotheses to justify this result are being investigated and may be related to the presence of vernix caseosa in the external auditory canal, lack of calibration of the equipment, poor probe tip placement or poor seal. Other possible related factors are being proposed in the literature, as mother’s smoking habits and drug abuse; a recent study concluded that these two factors affect the outcome of OAE results (biasing towards a false-positive), such that if the mother is a smoker and/or drug user, her newborn has a higher chance of failing the OAE hearing screening test due to a conductive component [34]. These possible risk factors lack, however, strong evidence and still need to be investigated.

On the other hand, the high prevalence of sensorineural hearing impairment verified in children without risk factors for hearing loss confirms the need to screen every single newborn. This result was verified in several previous studies [1,4,5,35] being the main motivation for the universality of the screening programs.

Limitations

As limitations of our study we can list the following: those inherent in a retrospective study, as the selection and information bias; all our data is reliant upon provider-reported input; the presence of cases lost to follow up, so the prevalence of hearing loss in the studied population is probably underestimated.

Conclusion

The total prevalence of hearing loss in our newborn population was 3.4 per 1000 births. The most common risk factors were ototoxic medications, preterm birth, familial hearing loss, very low birth weight and low Apgar scores. We concluded that the high percentage of children with sensorineural hearing loss in the absence of any known risk factor demonstrates the need to screen all neonates. Further studies are warranted to clarify the role of each risk factor in the hearing loss physiopathology.
