\begin{abstract}

The origin of dramatically different electron distributions responsible for Comptonization in black hole X-ray binaries (BHBs) in their various states is discussed. We solve the coupled kinetic equations for photons and electrons without approximations on the relevant cross-sections accounting for Compton scattering, synchrotron radiation, and Coulomb collisions. In the absence of external soft photons, the electrons are efficiently thermalized by synchrotron self-absorption and Coulomb scattering even for pure nonthermal electron injection. The resulting quasi-thermal synchrotron self-Compton spectra have very stable slopes and electron temperatures similar to the hard states of BHBs. The observed hard X-ray spectral slopes, the cutoff at 100 keV, and the MeV tail together require low magnetic fields, ruling out the magnetic dissipation mechanism. The motion of the accretion disk toward the black hole results in larger Compton cooling and lower equilibrium electron temperature. Our self-consistent simulations show that in this case both electron and photon distributions attain a power-law-dominated shape similar to what is observed in the soft state. The electron distribution in the Cyg X-1 soft state might require a strong magnetic field, being consistent with the magnetically dominated corona.

\textit{Key words}: accretion, accretion disks – black hole physics – gamma-rays: theory – methods: numerical – radiation mechanisms: non-thermal – X-rays: binaries

1. INTRODUCTION

The physical processes giving rise to the X-ray/gamma-ray emission of accreting black hole binaries (BHBs) have been a matter of debate over the last four decades. The hard-state spectra, showing a strong cut-off around 100 keV, are well described by thermal Comptonization (e.g., Poutanen 1998; Zdziarski & Gierliński 2004), while a weak MeV tail requires the presence of nonthermal particles (McConnell et al. 1997; Ling et al. 1997). The origin of seed soft photons for Comptonization is, however, much less clear. An apparent correlation between the spectral slope and the amount of thermal Compton reflection (Zdziarski et al. 1999) argues in favor of the accretion disk, while the observed optical/X-ray correlation (Motch et al. 1982; Kanbach et al. 2001) leans toward the synchrotron hypothesis (e.g., Fabian et al. 1982; Wardziński & Zdziarski 2001). Interesting questions are then: what stabilizes the X-ray spectral slope at $\alpha \sim 0.6-0.8$, and what fixes the temperature of the emitting plasma at $kT_e \sim 50-100$ keV (Zdziarski et al. 1997; Poutanen 1998; Zdziarski & Gierliński 2004)? Do the feedback from the cool accretion disk and the thermostatic properties of electron–positron pairs (Haardt & Maraschi 1993; Haardt et al. 1994; Stern et al. 1995; Malzac et al. 2001) play a role here? Or does the cooling by synchrotron radiation (Narayan & Yi 1995) act as a stabilizer?

In the soft state, BHB spectra are dominated by thermal disk emission of temperature $kT_{BB} \sim 0.4-1.5$ keV. At higher energies the spectrum is power-law-like and shows no signatures of the cut-off (Grove et al. 1998) extending possibly up to 10 MeV (McConnell et al. 2002). This emission is well described by Comptonization in almost purely nonthermal plasmas (Poutanen & Coppi 1998; Gierliński et al. 1999; Coppi 1999; Zdziarski et al. 2001; Zdziarski & Gierliński 2004). We can then ask why the electrons are nearly thermal in the hard state, and what causes such a dramatic change in the electron distribution when transition to the soft state happens.

Poutanen & Coppi (1998) proposed that the two states are distinguished by the way the energy is supplied to the electrons: by thermal heating, dominating during the hard state, and by nonthermal acceleration, operating in the soft state. However, their treatment of Coulomb collisions (using the \texttt{EQPAIR} code by Coppi 1992, 1999) was approximate, and they neglected the effect of synchrotron boiler, involving the emission and absorption of synchrotron photons, which can act as an efficient particle thermalizer (Ghisellini et al. 1988).

Ghisellini et al. (1998) studied for the first time the combined effect of the synchrotron boiler and Compton cooling on the electron distribution and photon spectra (but neglected Coulomb scattering). They considered a two-phase corona model (Haardt & Maraschi 1993; Haardt et al. 1994; Stern et al. 1995), where half of the high-energy radiation was assumed to be reprocessed by the disk to soft photons. As the actual geometry of the emitting region is not known, we start from pure synchrotron self-Compton models (i.e. with no external soft photons) and compute self-consistently the electron (positron) and photon distributions. We then investigate how the additional soft photons (e.g., associated with the inner radius of the cool accretion disk) affect the equilibrium distributions and compare the results of simulations with the data on Cyg X-1. The preliminary results of this study were presented by Vurm & Poutanen (2008a).

2. MODEL SETUP

We consider a black hole of mass $10 M_\odot$, typical for stellar-mass BHBs. We assume that the inner accretion flow is hot and almost spherical, corresponding to the advection-dominated (Narayan & Yi 1995; Abramowicz et al. 1995; Esin et al. 1997) or to the recently discovered luminous hot accretion flow solutions (Yuan 2003; Yuan & Zdziarski 2004). One expects that most of the gravitational energy release happens within about $R = 10 R_S = 3 \times 10^7$ cm (where $R_S = 2GM/c^2$ is the...
The total optical depth might be larger due to the produced pairs, but for parameters considered here, the amount of pairs is negligible. The released energy needs to be transferred to electrons via, e.g., Coulomb collisions with hot protons, collective plasma effects, magnetic reconnection, or shocks. We assume that the energy transfer to the electrons is given by a power-law injection function \( dN_e/(dtd\gamma) \propto \gamma^{-\tau_{inj}} \) extending in the Lorentz factor from \( \gamma = 1 \) to \( 10^3 \). To keep the Thomson optical depth of the electrons associated with protons \( \tau_p \) constant,3 the same number of electrons from the equilibrium distribution is removed from the system. In this case, the net power is \( L_{inj} = R^2 \langle p \rangle_{inj} = \langle \gamma \rangle_{inj} \langle \gamma \rangle_{eq} m_e c^2 \), where \( \langle \gamma \rangle_{inj} \) and \( \langle \gamma \rangle_{eq} \) are the mean Lorentz factors of the injection function and of the equilibrium distribution, respectively, and \( N_e \) is uniquely determined by the model parameters and \( \langle \gamma \rangle_{eq} \).

The injected electrons are cooled by synchrotron emission and Compton scattering at timescales much shorter than the accretion time. The synchrotron radiation is strongly self-absorbed up to hundreds of harmonics, and therefore the cooling depends strongly on the high-energy tail of the electron distribution (see, e.g., Wardziński & Zdziarski 2001). The importance of synchrotron processes is determined by the ratio \( \eta_B = U_B R^2 c/L_{inj} \), where \( U_B = B^2/(8 \pi) \) is the magnetic energy density and \( L_{inj} \approx \frac{R^2}{\pi} \rho \gamma \) (so that \( \eta_B \approx 3/4 \pi \approx 0.25 \) corresponds to an equipartition of the magnetic and radiation energy densities, \( U_B = U_{rad} \)). The seed photons for Compton upscattering can be provided by the synchrotron as well as by the external sources, the cool accretion disk being the most natural one. The external soft photons are modeled as a black body of temperature \( T_{BB} \) determined from the Stefan–Boltzmann law \( L_{disk} = 4\pi R^2 \sigma_T T_{BB}^4 \). The cooling by external photons depends on the ratio \( f = L_{disk}/L_{inj} \). The total escaping photon luminosity is \( L = L_{disk} + L_{inj} = (1 + f)L_{inj} \).

To model self-consistently particle and photon distributions, we solve numerically a set of coupled, time-dependent kinetic equations for photons, electrons, and positrons describing Compton scattering, cyclo-synchrotron emission and absorption, electron–electron Coulomb (Møller) scattering as well as pair production and annihilation. Our calculations are done in a simple one-zone geometry with a tangled magnetic field and isotropic particle and photon distributions. The escape probability formalism is used to simulate photon escape from the region. The detailed description of the code and its extensive testing are given in Vurm & Poutanen (2008b).

3. SYNCHROTRON SELF-COMPTON MODELS

We first assume that the cool disk is sufficiently far away and does not supply any seed soft photons to the inner hot flow. Thus, we consider pure synchrotron self-Compton (SSC) models (\( f = 0 \)). We choose the fiducial parameter set \( L = L_{inj} = 10^{37} \text{ erg s}^{-1} \) and \( \tau_p = 1.5 \) (typical for the hard state of BHB, Zdziarski et al. 1997), \( R = 3 \times 10^7 \text{ cm}, \Gamma_{inj} = 3 \) (ad hoc), and \( \eta_B = 1 \). The equilibrium electron distribution consists of a Maxwellian part with \( k T_e = 66 \text{ keV} \) and a power-law-like tail with the slope modified by cooling \( \Gamma_e = \Gamma_{inj} + 1 = 4 \) (where \( dN_e/d\gamma \propto \gamma^{-1}; \) see the solid curve in Figure 1(a')). The synchrotron emission is strongly self-absorbed with only the nonthermal tail above \( \gamma \gtrsim 20 \) contributing to emission above the self-absorption energy at \( \gtrsim 10 \text{ eV} \). As the amount of seed soft (synchrotron) photons is low, the Comptonization spectrum (produced predominantly by the thermal electron population) is hard with the photon energy index \( \alpha \approx 0.9 \) and a cut-off at \( \sim 100 \text{ keV} \), which is similar to the hard state of BHBs. A tail produced by single-Compton scattering off the power-law electron tail is clearly visible above MeV.
The soft state can be described by $\gamma_{\text{inj}}$ for an extended energy interval (Katarzyński et al. 2006). Absorbed, while the energy losses and gains stay close to each emission produced by these electrons is still strongly self-absorbed, with the photon energy index $\alpha \lesssim 0.7$ (see dashed curves in Figure 1(a)). A high injection gives more power to the nonthermal tail and more seed photons for Comptonization (see also Ghisellini et al. 1998; Wardziński & Zdziarski 2001), which causes a drop in the electron temperature (see the dotted curves in Figure 1(a)). A strong “bump” also develops in the tail of the electron distribution at $\gamma \sim 3$. The synchrotron emission produced by these electrons is still strongly self-absorbed, while the energy losses and gains stay close to each other for an extended energy interval (Katarzyński et al. 2006). In this regime, the ratio of synchrotron heating and cooling rates for a power-law distribution of relativistic electrons is $\gamma_{\text{inj}}/\gamma_c \approx 5/(\Gamma_c + 2)^2$. Observe that for $\Gamma_c = 3$ (i.e. for $\Gamma_{\text{inj}} = 2$) the heating and cooling rates are balanced; however, such an equilibrium is unstable (Rees 1967). The Comptonized spectrum for hard injection $\Gamma_{\text{inj}} = 2$ (see Figure 1(a)) is much softer than the hard-state spectra of BHBs, even without any contribution to the cooling from the disk, strongly constraining the electron injection mechanism in BHBs.

The efficiency of synchrotron cooling depends on the magnetic field strength parameterized here via magnetization $\eta_B$. At small $\eta_B$ (see Figure 1(b’)), synchrotron is inefficient, and cooling is dominated by thermal Comptonization. A higher normalization of the power-law part of the equilibrium electron distribution leads to a stronger MeV tail. For $\eta_B \leq 1$ (and $\Gamma_{\text{inj}} > 3$), the thermal Comptonization spectrum is very stable with $\alpha \sim 0.7–0.9$. At large $\eta_B > 1$, the synchrotron thermalization operates more efficiently, and the thermal part of the distribution persists to higher energies. The increasing $B$ field compensates for the decrease in the power-law tail leading to a higher synchrotron emission, which results in softening of the Comptonized spectrum.

Consider now variations of $\tau_p$ for fixed $L_{\text{inj}}$. At high $\tau_p$, the equilibrium electron temperature drops, leaving fewer energetic electrons for synchrotron emission and, therefore, reducing the number of seed photons for Comptonization (Figure 1(c)). This, in turn, results in the harder photon spectra produced by saturated Comptonization (by thermal electrons) and a weak high-energy tail (produced by nonthermal electrons), very similar to the ultrasoft spectra of BHBs (see Figures 8 and 9 in Zdziarski & Gierliński 2004). At smaller $\tau_p$, the higher electron temperature leads to a stronger synchrotron cooling and to a lower Comptonized luminosity and, therefore, softer Comptonized spectra.

Let us now apply the developed model to the hard state of Cyg X-1. The MeV tail observed there with $\alpha_{\text{MeV}} \approx 2$ (McConnell et al. 2002) constrains the injection slope to be $\Gamma_{\text{inj}} \lesssim 2\alpha_{\text{MeV}} = 4$. Then the hard X-ray spectra with $\alpha \lesssim 0.7$ and a high-energy cutoff at $\sim 100$ keV (see Figure 2) require $\tau_p \sim 1$ and low $\eta_B \lesssim 0.1$ (see also Wardziński & Zdziarski 2001; McConnell et al. 2002). Any additional soft photons from the disk will make the spectrum softer, reducing $\eta_B$ even more. The low magnetic field rules out magnetic reconnection as the energy dissipation mechanism. This also implies that electrons cannot be thermalized by the synchrotron self-absorption. On the other hand, if the size of the active region is $R \sim 60R_g$, Coulomb scattering becomes important (as its influence grows linearly with size for constant $L$, see, e.g., Coppi 1999; Svensson 1999), and it can thermalize electrons at a rather high temperature of $kT_e \sim 100$ keV as observed in Cyg X-1 (Gierliński et al. 1997; Poutanen 1998).

We reiterate that the whole spectrum here is produced by the SSC mechanism. Its thermostatic properties fix the electron temperature at $50–100$ keV (for $\tau_p \sim 1$) and stabilize the spectral slope at $\alpha \sim 0.7–0.9$. The feedback from the disk (Haardt & Maraschi 1993; Haardt et al. 1994; Stern et al. 1995; Malzac et al. 2001) does not seem to be needed.

4. SPECTRAL TRANSITIONS AND THE ROLE OF DISK PHOTONS

The spectral transitions observed in BHBs are most probably accompanied by a change in the geometry of the accretion disk. The cool outer disk moves toward the central black hole, causing an increasing flux of soft photons to the central hot flow (Esin et al. 1997; Poutanen et al. 1997; Poutanen & Coppi 1998), which we simulate here by increasing $f$ (see Figure 1(d)). Higher soft photon flux leads to faster Compton cooling and lower equilibrium electron temperature, making the nonthermal part more pronounced. The resulting photon distribution changes from the hard, thermal Comptonization dominated, spectrum to the one dominated by the disk blackbody, with a nonthermal tail extending to tens of MeV, which becomes harder at higher $f$. The spectral changes triggered by varying $f$ are similar to the one observed in Cyg X-1 (see Figure 2). A detailed comparison with Cyg X-1 spectra shows, however, that other parameters change too.

Compared to the hard state, the soft state corresponds to a higher total luminosity. The MeV tail is harder, $\alpha_{\text{MeV}} \approx 1.6$ (McConnell et al. 2002), and therefore $\Gamma_{\text{inj}} \sim 3.2$. If the tail of the blackbody at $3–10$ keV (see Figure 2) is produced in the same emission region, it requires a rather hot thermal

---

4. SPECTRAL TRANSITIONS AND THE ROLE OF DISK PHOTONS

The spectral transitions observed in BHBs are most probably accompanied by a change in the geometry of the accretion disk. The cool outer disk moves toward the central black hole, causing an increasing flux of soft photons to the central hot flow (Esin et al. 1997; Poutanen et al. 1997; Poutanen & Coppi 1998), which we simulate here by increasing $f$ (see Figure 1(d)). Higher soft photon flux leads to faster Compton cooling and lower equilibrium electron temperature, making the nonthermal part more pronounced. The resulting photon distribution changes from the hard, thermal Comptonization dominated, spectrum to the one dominated by the disk blackbody, with a nonthermal tail extending to tens of MeV, which becomes harder at higher $f$. The spectral changes triggered by varying $f$ are similar to the one observed in Cyg X-1 (see Figure 2). A detailed comparison with Cyg X-1 spectra shows, however, that other parameters change too.

Compared to the hard state, the soft state corresponds to a higher total luminosity. The MeV tail is harder, $\alpha_{\text{MeV}} \approx 1.6$ (McConnell et al. 2002), and therefore $\Gamma_{\text{inj}} \sim 3.2$. If the tail of the blackbody at $3–10$ keV (see Figure 2) is produced in the same emission region, it requires a rather hot thermal

---

5. ADAF-based models also consider SSC as the main cooling mechanism; see Narayan et al. (1998) for a review.
population of electrons, which needs high $\eta_B$ for the synchrotron thermalization to operate (because Coulomb thermalization is not efficient under the conditions of strong Compton cooling). This would be consistent with the magnetically dominated emission region. Alternatively, there may be additional heating mechanisms operating. Also the tail might be a result of the ultraviolet transitions in BHBs can be reproduced by varying the ratio $\eta_B$. At low $\eta_B$, the emission region. Alternatively, there may be additional heating, which is consistent with a magnetically dominated corona being responsible for the high-energy emission.

5. CONCLUSIONS

The hard state of BHBs can well be described by the quasi-thermal SSC mechanism. The feedback from the cool disk. The increasing Compton cooling causes dramatic changes in the electron distribution from almost purely thermal to nearly nonthermal. The photon distribution also changes from quasi-thermal SSC to the nonthermal Comptonization of the disk photons. In the soft state of Cyg X-1, a strong magnetic field can thermalize electrons at sufficiently high temperature, which is consistent with a magnetically dominated corona being responsible for the high-energy emission.
