We present a theory for the number fluctuations of a quasi-two-dimensional (quasi-2D) dipolar Bose-Einstein condensate (BEC) measured with finite resolution cells. We show that when the dipoles are tilted to have a component parallel to the plane of the trap, the number fluctuations become anisotropic, i.e. depend on the in-plane orientation of the measurement cell. We develop analytic results for the quantum and thermal fluctuations applicable to the cell sizes accessible in experiments. We show that as cell size is increased the thermodynamic fluctuation result is approached much more slowly than in condensates with short range interactions, so experiments would not require high numerical aperture imaging to observe the predicted effect.

PACS numbers: 67.85-d, 67.85.Bc

Many important aspects of a quantum system are revealed by studying its fluctuations. For instance, in quantum optics intensity fluctuations distinguish a laser from chaotic light [1], and reveal non-classical effects such as photon anti-bunching in resonance florescence [2]. With the rapid progress made in the experimental study of quantum gases, the measurement of fluctuations has become of increasing interest (e.g. see [3–14]). Particularly for the insight it provides into manybody physics, including non-equilibrium regimes where it is a critical tool for studying quenches [10, 15].

Here we study the fluctuations of a dipolar BEC, a system that promises a diverse range of new physics (e.g. [16, 17]) and has seen remarkable experimental progress with the production of chromium [18, 19], dysprosium [20] and erbium [21] condensates. The key new feature of these systems is that the atoms interact via a dipole-dipole interaction (DDI) that is both long ranged and anisotropic. The anisotropy manifests itself in the condensate density distribution (magnetostriction) [22, 23] and the excitation spectrum [24], and thus in the system coherence functions [25] and superfluid properties [26]. Additionally, the DDI is partially attractive and produces roton-like excitations in confined geometries [27–29] and enhances density fluctuations [30–33].

The atom number fluctuation measurements are performed in finite-sized cells, with minimum cell dimension being limited by the imaging system resolution (typically much larger than the BEC healing length). The crucial role that the cell plays in the measurement has been the subject of recent attention [12, 13, 34]. Tailoring the size and shape of the cell can be used to identify localised roton modes [32] and at sufficiently low temperatures (and for cells smaller than the thermal wavelength) the measurements will be dominated by quantum fluctuations of collective modes [13], predicted to exhibit non-extensive scaling with cell size [30, 35].

Focusing on the quasi-2D case of a dipolar BEC tightly confined in one direction we consider the measurement of number fluctuations in cells (c.f. fluctuation measurements of a non-dipolar BEC in [11, 15]). We demonstrate that the fluctuations are anisotropic, as schematically illustrated in Fig. 1(a): Two cells of identical geometry, but orthogonal orientations, measure identical mean atom numbers, however the number variances in these two measurements are strik-

![Fig. 1](image-url)
is the axial harmonic oscillator length. Considering magnetic cell weight function, and imaging along the direction we approximate the weight function from multiple pixels, e.g., as was done in Ref. [13]. The DDIs are momentum dependent, \( \alpha \) is the scattering length and \( L_z = \sqrt{\hbar/m\omega_z} \) is the axial harmonic oscillator length. Considering magnetic dipoles with a permanent moment \( \mu_m \), the quasi-2D DDI coupling constant is \( g_{\mu} = \mu_0 \mu_m^2/3\sqrt{2\pi}L_z \). The excitations are given by Bogoliubov theory

\[
E_k = \sqrt{\epsilon_k[\epsilon_k + 2n\tilde{V}(k)]},
\]

where \( k = (k_x, k_y) \), \( \epsilon_k = \hbar^2k^2/2m \), and \( \tilde{V}(k) = g + g_\mu F(kL_z/\sqrt{2}) \) is the \( k \)-space interaction potential between the dipoles. We have introduced the function

\[
F(q) = \cos^2 \alpha[2 - G(q)] + \sin^2 \alpha[-1 + G(q)(q_x/q)^2],
\]

where \( G(q) \equiv 3\sqrt{\pi}q e^{q^2} \text{erfc}(q) \), with \( \text{erfc} \) the complementary error function. For \( \alpha = 0 \) (untilted dipoles) we have \( F(q) = 2 - G(q) \) and the DDIs are momentum dependent, but isotropic. For \( \alpha \neq 0 \) the anisotropic term \( \propto (q_x/q)^2 \) contributes.

The in situ imaging of ultra-cold gases can be used to measure the atom number within finite-sized cells determined by the combined properties of the point spread function of the imaging system and the pixels of the camera used to capture the image [12, 13, 34]. The operator for atom number within such a cell is \( \tilde{N}_r = \int d^2r \sigma(r) \tilde{n}(r) \), where \( \sigma(r) \) is the cell weight function, and \( \tilde{n} \) is the density operator. Considering imaging along the \( z \) direction we approximate the weight function as the 2D Gaussian \( \sigma(r) = 2e^{-((x/L_x)^2-(y/L_y)^2)/2} \) with \( 1/e \) lengths \( L_x \) and \( L_y \) along \( x \) and \( y \), respectively. This cell has an effective area of \( A_r = 2\pi L_x L_y \) and an aspect ratio of \( \lambda \equiv L_y/L_x \). Having anisotropic cells (i.e. \( \lambda \neq 1 \)) is essential to probe the intrinsic anisotropy that emerges in the dipolar BEC and can be realised by amalgamating the signal from multiple pixels, e.g., as was done in Ref. [13].

The mean atom number per cell is \( N_\sigma = nA_r \) and only depends on the cell area (i.e. independent of \( \lambda \)). The variance in atom number \( \Delta N^2_\sigma \equiv \langle (\tilde{N}_\sigma - N_\sigma)^2 \rangle \) is given by [30, 35]

\[
\Delta N^2_\sigma = \int d^2r \tau_\sigma(r) (n^2g^2(r) - n^2) + n\delta(r),
\]

where \( g^2(r) = n^{-2}(\tilde{n}(r)\tilde{n}(r') : \cdots) \) is the density-density correlation function with \( r = r' \), \( S(k) = N^{-1}\langle \delta n_k \delta n_{-k} \rangle \) is the static structure factor, \( \delta n_k = \mathcal{F}\{\tilde{n}(\rho) - n\} \) is the density fluctuation operator, with \( \mathcal{F} \) the 2D Fourier transformation operator. The cell geometry function is \( \tau_\sigma(r) = \int d^2\rho \int d^2\rho' \sigma(\rho')\sigma(\rho)\delta(\rho - \rho' - r) \) with transform [30, 35]

\[
\tilde{\tau}_\sigma(k) = \mathcal{F}\{\tilde{\tau}_\sigma(r)\} = A_r^2e^{-[(k_xL_x)^2+(k_yL_y)^2]/2},
\]

for the Gaussian cell considered here. The static structure factor is given by the Feynman relation

\[
S(k) = \frac{\epsilon_k}{E_k} (2n\tilde{n}_k + 1),
\]

where \( \tilde{n}_k = 1/(e^{\beta E_k} - 1) \) and \( \beta = 1/k_BT \). This result is valid for dipolar BECs well below the condensation temperature [38] and for quasi-condensates [12, 39].

In Fig. 1(b) we consider the fluctuations using Eq. (4) as a function of cell area \( A_\sigma \) for cells with long axis parallel to the \( x \) (||) or \( y \) (\perp) directions. We show results for a tilted (\( \alpha = \pi/3 \)) and comparable\(^1\) untitled case (\( \alpha = 0 \)). The tilted results exhibit significantly larger fluctuations when the long axis of the measurement cell is parallel to the direction along which the dipoles tilt, as compared to the equivalent orthogonally oriented cell. These results show that this anisotropy is strongest for moderate-area cells, and is enhanced with temperature.

The behavior of \( \Delta N^2_\sigma \) is well understood for cells with dimensions either much larger or much smaller than the important system length scales, i.e. the healing length \( \xi = \hbar/\sqrt{\mu a} \) and the thermal wavelength:

\textbf{For small cells} – the number fluctuations are dominated by the high-\( k \) structure factor, which takes the uncorrelated value \( S(k) \approx 1 \) [see Fig. 3]. We can see this by noting that through the geometry function \( \tilde{\tau}_\sigma(k) \) the dominant contribution of \( S(k) \) to the number fluctuations (4) occurs for wave vectors \( |k_x|,|k_y| \ll 1/L_x,y \). Thus for small cells the uncorrelated quantum shot noise regime is obtained and the fluctuations are Poissonian, i.e. \( \Delta N^2_\sigma \rightarrow N_\sigma \) [see \( A_\sigma \rightarrow 0 \) in Fig. 1(b)].

Because it is difficult to resolve cells smaller than the system length scales with optical imaging, it is challenging to directly probe this regime in experiments.

\textbf{For large cells} – the fluctuations are determined by the \( k \rightarrow 0 \) structure factor, with \( S(0) = k_BT/\mu \) [see Fig. 3]. We thus recover the classical thermodynamic result \( \Delta N^2_\sigma/N_\sigma \rightarrow S(0) = nk_Tk_BT \), where \( k_T = 1/\mu a \) is the isothermal compressibility [i.e. \( T > 0 \) results as \( A_\sigma \rightarrow \infty \) in Fig. 1(b)].

\(^1\) The coupling constants are chosen so that both systems have the same values for \( \mu \) and \( g_{\mu} \cos^2 \alpha \).
The small and large cell limits discussed above have no geometry or anisotropy dependence, features that emerge for moderate-sized cells. In Fig. 2 we compute the fluctuation for moderately sized cells of fixed area $A_s = (60\xi)^2$ but varying aspect ratio $\lambda$. For both tilted and untitled dipoles the fluctuations depend on $\lambda$, however we distinguish two effects:

1. Geometry dependence: In general the fluctuations in microscopic cells depend on the shape of the cell, in contrast to the classical thermodynamic expression for macroscopic cells in which the fluctuations only depend on the cell area. Geometry dependence, e.g. surface area scaling of fluctuations for ideal fermions has been studied previously [30].

2. Orientation dependence: A key prediction is that the tilted dipolar system has anisotropic fluctuations, i.e. they depend on the cell orientation in the $xy$-plane. In our results [Fig. 2] this is revealed by asymmetry of the fluctuations under exchange of the cell dimensions $L_x \leftrightarrow L_y$ (i.e. $\lambda \leftrightarrow 1/\lambda$), particularly obvious at non-zero temperature [Fig. 2(b)].

We focus on the experimentally relevant regime of cells with dimensions $L_{x,y} \gg \xi$, where phonon modes dominate, and the role of temperature is characterised by the phonon thermal wavelength $\lambda_T \equiv h^2/mk_B T \xi$ [13, 30]. We develop an analytic model for this regime using expansions of the structure factors about $k = 0$ for $T = 0$

$$S(k) = \frac{1}{2} \xi k^2 [1 - n \nabla_k \tilde{V}(0) k/2\mu] + O(k^3), \tag{7}$$

and for $T > 0$

$$S(k) = \frac{k_B T}{\mu} [1 - n \nabla_k \tilde{V}(0) k/\mu] + O(k^2), \tag{8}$$

where $\nabla_k \tilde{V}(0) = -3g_d l_z \sqrt{2} [\cos^2 \alpha - (k_x/k)^2 \sin^2 \alpha]$ is the directional derivative of $\tilde{V}(k)$ along $k$ evaluated at $k = 0$. Both results are valid for $k \ll 1/\xi$, and additionally the finite temperature result also requires $k \ll 1/\lambda_T$. Result (7) is applicable to the $T \neq 0$ regime for wave vectors $k \gg 1/\lambda_T$, i.e. for $k$ values of phonons that are thermally unoccupied.

To first order in $k$ the quantum fluctuations (7) are isotropic (i.e. depend only on $k$), whereas the $T > 0$ result (8) is anisotropic if $\alpha \neq 0$. This anisotropy is apparent in the $k \to 0$ behaviour of $S(k)$ in Fig. 3(b): the slope has opposite signs along the $k_x$ and $k_y$ axes for our parameter choice, c.f. $S(k)$ at $T = 0$, which is clearly isotropic for small $k$. For the purely contact system ($g_d = 0$), $\nabla_k \tilde{V}(0) = 0$ and the leading order correction to $S(0)$ for $T > 0$ comes at quadratic order in $k$.

Evaluating (4) using the $T = 0$ result (7) yields the quantum fluctuations

$$\Delta N_2^2 / N_\sigma \approx \xi E(1 - \lambda^2) \lambda / \sqrt{A_\sigma}$$

$$+ \frac{n g_d}{\mu} 3 \pi (\pi/2)^{3/2} \lambda / \sqrt{A_\sigma} \left[ \cos^2 \alpha \left( \frac{1}{\lambda} \alpha + \lambda \sin^2 \alpha \right) \right], \tag{9}$$

valid for $\xi \ll L_{x,y} \ll \lambda_T$. In this regime, the fluctuations are dominated by quantum (unoccupied) phonon modes, and to leading order this gives a non-extensive scaling $\Delta N_2^2 \propto \sqrt{N_\sigma}$ [30, 35]. While accessing this regime is challenging, recent experiments in quasi-1D gases have come close enough to infer quantum corrections [13].

In the higher temperature regime we use result (8) to find

$$\Delta N_2^2 / N_\sigma \approx \frac{k_B T}{\mu} \left[ 1 + \frac{n g_d}{\mu} 3 \pi (\pi/2)^{3/2} \lambda / \sqrt{A_\sigma} \right] \left[ \frac{\cos^2 \alpha E(1 - \lambda^2)}{\sqrt{\lambda}} + \sin^2 \alpha E(1 - \lambda^2) - K(1 - \lambda^2) \lambda^{3/2} \right], \tag{10}$$

valid for $L_{x,y} \gg \max\{\xi, \lambda_T\}$, where $K(u)$ and $E(u)$ are complete elliptic integrals of the first and second kind respectively. The first right hand term $(k_B T / \mu)$ is the thermodynamic result for fluctuations, where the rest are leading order finite cell size corrections.

The predictions of results (9) and (10) are shown in Figs. 1 and 2, and are observed to provide a good description of the full numerical results for sufficiently large cells. These results also allow us to make some observations about the orientation dependence (the effect on fluctuations of $\lambda \leftrightarrow 1/\lambda$, i.e. rotating cell by $90^\circ$), noting that $E(1 - \lambda^2)/\sqrt{\lambda} = E(1 - \lambda^{-2})\sqrt{\lambda}$: (i) There is no orientation dependence for a contact gas (g_d = 0).

\[FIG. 2. (color online) Fluctuations as a function of cell aspect ratio with $A_s = (60\xi)^2$ for parameter set A ($\alpha = \pi/3$, $n g = 0.25\hbar_\omega z$, $n g_d = 0.4\hbar_\omega z$, black) and B ($\alpha = 0$, $n g = -0.05\hbar_\omega z$, $n g_d = 0.1\hbar_\omega z$, green) at (a) $T = 0$ with thin lines from Eq. (9), (b) $T = 2\mu/k_B$ with thin lines from Eq. (10).\]

\[FIG. 3. (color online) (a) Density-density correlation function and (b) static structure factors, at $T = 0$ (dashed lines) and $T = 2\mu/k_B$ (solid lines) for parameter set A defined in Fig. 2. (inset) Bogoliubov dispersion relation and free particle dispersion $\epsilon_k$ (gray). Along the $x, k_x$-axis (red) and along the $y, k_y$-axis (blue). Parameter set B results are isotropic and the same as parameter set A along the $k_y$ axis.\]
FIG. 4. (color online) Large $A_\sigma$ scaling of fluctuations as a function of cell area for dipolar BECs with $\alpha = \pi/3$ (A), $\lambda = 0.15$ (red) and $\lambda = 1/0.15$ (blue) and $\alpha = 0$ (B, green), comparing to a contact gas, i.e. $g_\sigma = 0$, with same $\mu$ (C, magenta dashed-dotted) at $T = 2\mu/k_B$. Thin lines are the analytic approximation (10) for A and B and (11) for C. Parameters A and B are detailed in Fig. 2.

0) or for an untitled dipolar gas ($\alpha = 0$) and by symmetry this is true for any cell size; (ii) The orientation dependence is enhanced for small $\mu$, however we note that we require $\mu \geq 0$ for the system to be stable.

Importantly our results demonstrate a key aspect of DDIs is to slow the approach to the thermodynamic result with cell size. This is demonstrated in Fig. 4 by comparing dipolar condensates to a condensate with purely contact interactions. Whereas the finite size corrections to the dipolar system scale as $\sim A_\sigma^{-1/2}$ as clearly seen from (10), the contact case converges more rapidly as $\sim A_\sigma^{-1}$. Indeed, for the contact case the fluctuations including the leading order finite size correction are

$$\frac{\Delta N^2}{N_\sigma} \approx \frac{k_B T}{\mu} + \frac{\pi \xi^2 (\mu - k_B T / \mu)}{2 A_\sigma} \left( \lambda + \frac{1}{\lambda} \right).$$

### Conclusions and outlook

We have developed a theory of fluctuation measurements made in dipolar condensates with finite-sized anisotropic measurement cells, providing analytic results for quantum and thermal fluctuations. A key prediction is that, by tilting the dipoles, anisotropy in the fluctuations arise. Our results show that this should be easily accessible in experiments, because (i) the system does not need to be close to the stability boundary (as is required to see rotons [27, 40]) and (ii) the effect persists for large cells (much greater than healing length), and thus does not require high numerical aperture imaging. We have shown that this latter effect is assisted by the slow onset of the thermodynamic limit (where anisotropy of fluctuations vanishes) as cell size increases, arising from the long range DDI. Through the use of a local density approximation [12, 13] (validated for DDIs in Refs. [32, 41]) our result is applicable to condensates in pancake shaped traps, or as in Ref. [11, 15] to the central region of such a system where the average density is approximately constant. Our predictions will be realisable with current experiments, e.g. parameter set A corresponds to $3.5 \times 10^5$ $^{164}$Dy atoms with $a_s = 4 \text{ nm}$ in a $\omega_{x,y} \omega_z = 2\pi \times (10, 1900) \text{ s}^{-1}$ trap (c.f. [11]), and the results in Fig. 2 are for a cell of area $A_\sigma \approx 800 \mu m^2$.
