Abstract. Structural and magnetic characterization of Mnₓ⁻ₓAl₁₀₀⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ₓ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻ˣ⁻xmmelt-spun ribbons is reported. To obtain the metastable ferromagnetic \( \tau \)-phase, rapidly solidified alloys were annealed either in a vacuum furnace at 823 K or directly in the vibrating sample magnetometer under applied magnetic field. Optimal magnetic properties were demonstrated by Mn₅₄Al₄₄C₂ samples proved to be single-phase with a coercivity of 0.19 T measured in both cases. For this composition the structural \( \varepsilon \rightarrow \tau \) phase transformation has been magnetically detected at 786 K, Curie temperature of \( \tau \)-phase \((T_c = 592 \text{ K}, T_p = 610 \text{ K})\) has been determined using mean field approximations in ferromagnetic and paramagnetic regions. Rietveld refinement of X-ray diffraction spectra was employed to analyse the phase constitution of annealed alloys, lattice parameters as a function of chemical composition and mean grain size for the phases involved.

1 Introduction

Mn-Al alloys are attractive candidates for permanent magnet applications due to good magnetic properties (superior to conventional ferrites), high technological properties (mechanical strength, machinability, corrosion resistance) and low cost (no rare earth elements). The ferromagnetic tetragonal \( \tau \)-phase with strong uniaxial magneto crystalline anisotropy \([1, 2]\) forms from the non-magnetic hexagonal \( \varepsilon \)-phase by annealing a quenched alloy with 50-60 \% of Mn at approximately 823 K. Both phases are metastable at room temperature and therefore need special thermal treatment. Carbon addition stabilizes \( \tau \)-phase and facilitates production of commercial anisotropic materials by hot deformation \([3]\). Magnetic hysteresis of Mn-Al-C alloys is sensitive to the microstructure and presence of defects developed during \( \tau \)-phase formation, comprising martensitic or massive transformation mechanisms \([4]\), and is therefore strongly influenced by the production route.

Various production techniques have been employed for preparation of homogeneous Mn-Al-C alloys: melt-spinning \([5-7]\), levitation melting with splat quenching \([8]\), spark erosion \([9]\), ball milling \([10, 11]\), mechanical grinding \([12]\). Depending on the solidification rate or size reduction degree, fine-grained materials with improved functional properties can be obtained. In this paper we report on the structural and magnetic characterization of Mn-Al-C melt-spun ribbons. The goal is to investigate a correlation between the production route, phase constitution and resulting hard magnetic properties.

Using accurate X-ray crystallographic analysis and magnetization measurements in a wide temperature range, we have advanced our understanding of structural and magnetic phase transitions in Mn-Al-C system and particular role of carbon.

2 Experimental

Binary alloys Mn₅₀Al₅₀ and Mn₅₅Al₄₅, as well as their ternary counterparts doped with carbon Mn₅₀Al₅₀C₂ and Mn₅₅Al₄₅C₂ were selected for the present study. The ingots prepared by induction melting were cast into \( \sim 3 \text{ mm} \) wide and \( \sim 25 \mu \text{m} \) thick ribbons using a melt-spinning technique. The details of sample preparation can be found in \([6]\). Final annealing was done in a vacuum furnace at 823 K for 10 min with ramping rate 10 K/min or directly in the magnetometer cell. Crystal structures were examined by a PANalytical X’Pert Pro X-ray diffractometer (XRD) in Co-K\( \alpha \) radiation equipped with an X’Celerator linear detector. Rietveld full-profile analysis of XRD spectra was performed using MAUD software \([13]\). Magnetization curves were recorded on a Lake Shore 7400 Series vibrating sample magnetometer (VSM) equipped with a variable temperature assembly.

3 Results and discussion

3.1 Phase analysis

The phase composition of rapidly solidified ribbons has been determined by XRD both in the as-quenched state (AQ) and after subsequent heat treatment (HT) as
described above. According to the phase diagram of Al-Mn system [14], formation of two equilibrium phases is expected: disordered cubic $\beta$-phase (cP20) with excess of Mn and ordered trigonal $\gamma_2$-phase (hR26) with excess of Al. In addition, two metastable phases may appear in non-equilibrium conditions: disordered hexagonal $\epsilon$-phase (hP2) and ordered tetragonal $\tau$-phase (tP2). Stable at higher temperatures, $\epsilon$-phase can be preserved on quenching and transformed into ferromagnetic $\tau$-phase by a composition-invariant (involving only short-range diffusion) structural transition. Depending on the initial chemical composition and thermal history, all these phases were observed in different combinations. Figure 1 presents XRD spectra from the as-quenched samples, while Figure 2 shows them after annealing at 823 K.

![Figure 1. XRD patterns of the as-quenched samples.](image1)

The results of quantitative phase analysis based on Rietveld refinement of XRD data are presented in Table 1. The weight fraction and lattice parameters for each observed crystal structure have been determined. As-quenched equiatomic alloy Mn$_{50}$Al$_{50}$ is composed entirely of $\gamma_2$-phase which remains also after annealing. The presence of carbon in Mn$_{50}$Al$_{50}$C$_2$ helps to retain some amount of $\epsilon$-phase subsequently transforming to $\tau$-phase. However, $\gamma_2$-phase persists and is not substantially affected by heat treatment. On the other hand, Mn-rich composition Mn$_{55}$Al$_{45}$ is more favourable for $\epsilon$-phase formation. In this case, however, $\beta$-phase precipitates along with desirable $\tau$-phase on annealing. Finally, positive influence of carbon allows to obtain a 100% $\tau$-phase in ternary Mn$_{54}$Al$_{44}$C$_2$ sample.

![Figure 2. XRD patterns of the samples annealed at 823 K.](image2)

As seen in Table 1, addition of carbon slightly increases both lattice parameters of $\epsilon$-phase, while in $\tau$-phase it leads to decrease of $a$ and pronounced (~1.5%) increase of $c$. The unit cell volume also increases. Though C has been reported to occupy ($\frac{1}{2},\frac{1}{2},\frac{1}{2}$) sites together with Al [15], this observation provides a new evidence for presence of carbon atoms in the interstitial positions (0,0,1/2) and ($\frac{1}{2},\frac{1}{2},0$) of tetragonal $\tau$-phase [10, 16] similar to Fe-C martensite.

### Table 1. Nominal composition of the melt-spun samples and XRD phase analysis (weight fraction, lattice parameters) in the as-quenched state (AQ) and after heat treatment at 823 K (HT).

| Composition, at.% | State | $\epsilon$-phase | $\tau$-phase | $\gamma_2$-phase | $\beta$-phase |
|------------------|-------|------------------|--------------|------------------|--------------|
| | | wt. % | $a$, Å | $c$, Å | wt. % | $a$, Å | $c$, Å | wt. % | $a$, Å |
| Mn | Al | C | | | | | | |
| 50 | 50 | – | AQ | – | – | – | – | 100 | 12.59 | 7.898 | – | – |
| | | | HT | – | – | – | – | 100 | 12.57 | 7.897 | – | – |
| 49 | 49 | 2 | AQ | 58 | 2.711 | 4.388 | 70 | 2.767 | 3.619 | 42 | 12.61 | 7.918 | – | – |
| | | | HT | – | – | – | 30 | 12.59 | 7.916 | – | – |
| 55 | 45 | – | AQ | 100 | 2.703 | 4.373 | 75 | 2.775 | 3.574 | – | – | – | 25 | 6.437 |
| | | | HT | – | – | – | – | – | – | – | – | – | – |
| 54 | 44 | 2 | AQ | 100 | 2.709 | 4.389 | – | – | – | – | – | – | – | – |
| | | | HT | – | – | – | 100 | 2.762 | 3.638 | – | – | – | – | – | – |
The mean size of reflecting crystallites determined from line broadening is 100–150 nm for most phases. Exception is ε-phase having large crystallites of ~600 nm and a noticeable (0 0 1) preferred orientation in as-quenched samples which may be attributed to a columnar microstructure. Further refinement of grain size can be achieved by increase of the cooling rate in the melt-spinning setup.

3.2 Magnetic properties

Magnetic measurements were performed on rapidly solidified ribbons in the as-quenched state, after heat treatment in the furnace, and also during in-situ heating/cooling in VSM.

Figure 3 presents the room temperature magnetization curves of three samples having ferromagnetic behaviour; other samples showed very low values of magnetization. These results agree well with XRD data (Table 1) as τ-phase responsible for hard magnetism is observed after annealing only in Mn₅₅Al₄₅, Mn₅₄Al₄₄C₂ and Mn₄₉Al₄₉C₂. Moreover, there is a correlation between the weight fraction of τ-phase determined from XRD and the saturation magnetization extracted from VSM measurements. Single-phase alloy Mn₅₄Al₄₄C₂ has the highest magnetization and better coercivity of 0.19 T compared to binary alloy Mn₅₅Al₄₅. Two-phase alloy Mn₄₉Al₄₉C₂ displays lower magnetization and higher coercivity of 0.23 T. Our coercivity values are higher than 0.17 T [6] and 0.15 T [7] reported for other rapid solidification attempts, but lower compared to 0.48 T [10] achieved in a ball milled powder. However, pure τ-phase can be difficult to obtain in mechanically activated nanostructured material [10].

Figure 4 shows the magnetization of as-quenched Mn₅₄Al₄₄C₂ sample as a function of temperature under a constant magnetic field of 1.4 T. The ramps were performed between 300 K and 900 K at 5 K/min rate. Precursor ε-phase is antiferromagnetic below 97 K [17] and paramagnetic at initial room temperature. On heating, ε-phase transforms to τ-phase which is also paramagnetic at the transition temperature ~786 K (see the inset). The structural transition is detected due to a difference in magnetic susceptibility of the phases. On cooling, magnetization is increased drastically below Curie temperature of τ-phase as the reverse transition to ε-phase does not occur, probably, due to kinetic reasons.

Figure 5 illustrates the precise determination of Curie temperature from the magnetization measurements in ferromagnetic and paramagnetic states of τ-phase.

06008-p.3
used follow from the temperature dependence of magnetic susceptibility in the mean field theory: \((T - T_p)^{-1}\) in paramagnetic region and \((T_c - T)^{1/2}\) in ferromagnetic region. Calculated temperatures \(T_p\) and \(T_c\) correspond well, satisfying usual inequality \(T_p > T_c\). Thus, the variable temperature VSM experiment allows to observe \(\varepsilon \rightarrow \tau\) phase transition, receive \(\tau\)-phase (under magnetic field) for further investigation and measure its Curie temperature by two methods.

In Mn-Al-C alloys Curie temperature of \(\tau\)-phase decreases with carbon doping, available data largely vary \([6, 7, 10]\). Taking into account this dependence, we find good agreement of our \(T_c\) measurements with results of Zeng et al. \([10]\). The coercivity of Mn54Al44C2 sample subjected to \textit{in situ} annealing is 0.19 T, \(i.e.\) equals to that after furnace annealing, and increases to 0.23 T on cooling down to 100 K.

4 Conclusions

Melt-spinning technique enabled us to produce homogeneous single-phase precursors for Mn-Al-C permanent magnets, though higher cooling rate is desirable for reducing the grain size. The metastable ferromagnetic \(\tau\)-phase has been obtained by annealing non-magnetic \(\varepsilon\)-phase samples either in a vacuum furnace at 823 K for 10 min or directly in the vibrating sample magnetometer under applied magnetic field. Among the studied alloys, best magnetic properties are demonstrated by Mn54Al44C2 samples due to the positive effect of carbon on the stability of \(\tau\)-phase and domain wall pinning by fine carbide precipitates. The coercivity decreases with temperature from 0.23 T at 100 K to 0.19 T at 300 K and is independent on the annealing method (with or without field). On heating in VSM Mn54Al44C2 alloy undergoes the structural \(\varepsilon \rightarrow \tau\) phase transformation at 786 K, on cooling Curie temperature of \(\tau\)-phase \((T_c = 592 K, T_p = 610 K)\) is determined using mean field approximations in ferromagnetic and paramagnetic regions. The results of magnetization measurements are in good agreement with XRD quantitative phase analysis based on Rietveld refinement. The tetragonal distortion of \(\tau\)-phase unit cell has been confirmed to increase with carbon content, which suggests a possible presence of carbon atoms in the interstitial positions similar to Fe-C martensite.
