Background: The aim of this study was to determine whether mRNA expressions and dynamic changes of immune-related genes before and after starting first-line treatment with the PD-1 inhibitor pembrolizumab in patients with NSCLC were of predictive value.

Methods: CD3, CD8, PD-1, PD-L1 and CTLA-4 mRNA expression levels were measured from peripheral blood before and after three weeks of treatment with the PD-1 inhibitor. Univariate and multivariate analyses were performed retrospectively. Response, progression-free survival (PFS) and overall survival (OS) were determined.

Results: In univariate analysis an increase of CD3 and CD8 mRNA expression after the first cycle of pembrolizumab were each associated with improved PFS and OS. In contrast, patients with no change or with a decrease in CD3 and CD8 mRNA expression showed significantly worse outcome. CD8 mRNA increase remained an independent predictive factor for PFS and OS in the multivariate analysis with p values of 0.011 and 0.006, respectively.

Conclusions: An increase of CD8 mRNA expression predicts favorable outcome after first line monotherapy with pembrolizumab, while no change or decrease might serve as an indicator of poor outcome and might give cause for early treatment escalation for instance by addition of chemotherapy or additional ICI treatment, e.g., against CTLA-4.

**Introduction**

Immune-checkpoint inhibitors (ICI) directed against programmed death 1 (PD-1), programmed death ligand 1 (PD-L1) or cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) have expanded the treatment options for advanced NSCLC. In patients without drugable driver mutations ICI were first approved for palliative 2nd and 3rd line treatment of metastatic NSCLC (1-5). Up to 16% of NSCLC patients receiving an ICI as palliative 2nd or 3rd line treatment survive for more than five years (6). Nowadays, ICI either alone or as combination therapy with chemotherapy are established in the 1st line setting. Especially, the PD-1 ICI pembrolizumab is approved in Europe as a 1st line monotherapy for patients with an immunohistochemically based tumor proportion score (TPS) for PD-L1 ≥50% after data from the registrational phase III trial KEYNOTE-024 showed superior results in comparison to a chemotherapy only control arm in terms of its primary endpoints PFS and OS (7). Recently, 5-year survival data were reported with 31.9% of patients living after 1st line treatment with this ICI in contrast to 16.3% with a chemotherapy only first-line treatment (HR 0.62) (8). However, in about one third of patients there is no long lasting benefit due to early progression, hyperprogression or serious adverse events (9). Therefore, it would be of utmost importance to have reliable predictive factors showing non-effectiveness of ICIs before the first radiological measurement of response is possible.

Beside PD-L1 tumor proportional score (TPS) analyzed immunohistochemically from the tissue biopsy before treatment there is no officially accepted clinical factor or biomarker to date (10). Various biomarkers including high tumor mutational burden (TMB) have been tested and reported to be associated with a better response rate and an increased survival (11). However, there is a lack of standardization between the testing platforms used and a lack of a fixed TMB threshold so far (12). Therefore, blood-based biomarkers, which can be obtained noninvasively and can easily be repeated came into focus (10). Using peripheral blood laboratory values, e.g., C-reactive protein (CRP) or the neutrophile-lymphocyte ratio (NLR) might be of predictive value during monotherapy with ICI (13,14). It was shown that both a decrease in CRP values and a decrease in the NLR ratio were associated with a good outcome in terms of PFS and even OS (14,15). However, these markers are rather unspecific with regard to response of specific immune cell types being affected by the therapy as they cannot distinguish, e.g., regulatory T-cell expansion from natural killer cell expansion upon ICI treatment, which might indicate inverse reactions and outcome. In line with these assumptions, dynamic changes of molecular markers in a so called liquid biopsy (LB), e.g., loss of ctDNA during ICI therapy or increase in CD8+PD-1+ cells in the peripheral blood might be of essential relevance as they reflect the very early response (16-20). However, those studies are hardly comparable due to small case numbers, patients in different lines of treatment with different PD-1 and PD-L1 directed antibodies and different time intervals used for the observation of the dynamic change. Moreover, FACS based methodologies are too complex for clinical routine and are sensitive to pre-analytical sample preservation and of limited robustness in view of reagent variations.

Therefore, we aimed to analyze immune-related markers in a homogenous cohort of NSCLC stage IV patients with high TPS score of at least 50% in their tumors being treated by the PD-1 antibody pembrolizumab in a 1st line setting. Whole blood samples were prospectively taken before start of ICI and after three weeks of treatment. In this analysis we report on pre-treatment mRNA expressions and dynamic changes of CD3, CD8, PD-1, PD-L1 and CTLA-4 after the first application of pembrolizumab using a commercially available kit. We present the following article in accordance with the STROBE reporting checklist (available at https://dx.doi.org/10.21037/tlcr-21-587).

**Methods**

**Design of the study**

This retrospective analysis studies predictive markers for efficacy under a palliative 1st line treatment with the ICI pembrolizumab in patients with metastatic NSCLC. Peripheral blood samples were taken prospectively before and during treatment with pembrolizumab. Patients had to have a histologically proven NSCLC UICC stage IV according to the 8th edition of the UICC TNM classification. Patients with a history of adjuvant chemotherapy before 1st line palliative therapy could be included if there was an interval of more than 12 months between the adjuvant treatment and the first systemic treatment for stage IV disease. Patients with a history of palliative radiation therapy could also be enrolled into the study. NSCLC with a non-squamous histology were tested for EGFR mutations and ALK translocations and were...
excluded in case of a positive result. Patients had to have a PD-L1 TPS score from the tumor biopsy of $\geq 50\%$ to qualify for 1<sup>st</sup> line pembrolizumab according to the approval status of pembrolizumab in Germany.

Treatment was performed at a German tertiary high-volume lung cancer center (Nuremberg) with specialization in thoracic oncology and strong experience in chemo- and immune-oncology therapy. Patients were treated with pembrolizumab between February 2017 and October 2020, which allowed for a follow-up of at least six months prior to the data cut-off of April 30<sup>th</sup>, 2021. Data were recorded in a standardized manner with the following data being collected for each patient: age, sex, tumor stage, histology, performance status according to Eastern Cooperative Oncology Group performance status (ECOG-PS), PD-L1 tumor proportional score (TPS) determined by immunohistochemistry (marker ZR3), mutational status (for non-squamous tumors) determined by next-generation sequencing (NGS), date of NSCLC diagnosis, survival status at time point of documentation (alive or deceased) and date of last contact/death. For ICI treatment the following details of therapy were documented: date of start, number of treatment cycles, best response, date of progression and reason for treatment stop.

This study was approved by the Ethics committee of the Friedrich-Alexander-University Erlangen-Nuremberg, Germany (numbers: 56_16B and 62_17B). Written informed consent for blood taking, collecting and analyzing for research purpose was obtained from every patient. The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013).

**PD-L1 immunohistochemistry**

The tissue slides were incubated with antibodies against PD-L1 (clone ZR3; Medac, Wedel, Germany; 1:100 in dilution) using the Dako Agilent Link 48 auto-stainer according to the manufacturer's standard recommendations. PD-L1 expression on tumor cells was counted by scoring the proportion of any membranous positive tumor cells over the total number of tumor cells (tumor proportion score, TPS), and grouped into four categories (<1% negative, 1–49% weak positive, 50–74% strong positive and $\geq 75$ very strong positive). In addition, the exact percentage of the TPS was noted (21,22). The antibody ZR3 had been validated against 22C3 at our department and concordance with 22C3 was very high. An example of the immunohistochemical staining with both antibodies is given in Figure 1. In addition, after passing two German external quality assessments for PD-L1 staining the pathological department received approval with ZR3. In contrast to FDA companion diagnostic with 22C3 for use of pembrolizumab is not prescribed by the EMA in Europe.

**RNA isolation and quantitative reverse transcription-polymerase chain reaction (QRT-PCR assessment)**

RNA was extracted from whole blood samples according to general instruction for use of the commercially available bead-based extraction method (Xtrakt kit; Stratifyer Molecular Pathology GmbH, Cologne, Germany). In brief, 100 µL blood were put into a 1.5 mL microcentrifuge tube and 100 µL red cell lysis buffer was added to incubate for 15 minutes at 95 °C with shaking at 100 rpm in a thermomixer. Thereafter, the lysate was treated with proteinase K for 15 min at 65 °C. Subsequently binding buffer and magnetic beads were added and incubated for 15 min at room temperature with shaking at 1,200 rpm. Supernatant was discarded and the beads were washed by three cycles of adding wash buffer, aspiration, magnetization and discarding the supernatant. Finally, nucleic acids were diluted by adding 100 µL elution buffer and incubation at 95 °C for 15 min while shaking at 1,000 rpm. Thereafter, the beads were magnetized and the supernatant was DNase I digested to receive DNase free total RNA from the specimen. RNA eluates were then stored at −80 °C until use. The mRNA levels of CD3Z, CD8A, PD-1, PD-L1, CTLA-4 and the reference genes Calmodulin2 (CALM2) and Beta-2 microglobulin (B2M) were determined by a one-step RT-qPCR using the SuperScript III RT-qPCR
Gene expression levels were calculated as \( \Delta \Delta Cq \). The median age at least every 3 months or upon clinical deterioration.

Each patient sample or control was analyzed in duplicate in a Light Cycler LC480 Instrument II (Roche Diagnostics, Rotkreuz, Switzerland) according to the manufacturers’ instructions with 30 min at 50 °C, 2 min at 95 °C followed by 40 cycles of 15 s at 95 °C and 30 s at 60 °C, according to MammaTyper® instructions for use 140603-90020-EU Rev 2.0. Gene expression was quantified with a modification of the method by Schmittgen and Livak by calculating 

\[ 40 - \Delta \Delta Cq = 40 - (Cq(MG) - Cq(REF)) \]

where \( \Delta Cq \) was calculated as the difference in Ct between the test gene and the mean of the reference genes (23). Gene expression levels were calculated as described before. In short, cycle quantification threshold (Cq) values of marker genes (MG) for each sample (S) were estimated as the median of the triplicate measurements. To correct for inter-run variations Cq values were normalized against the mean expression of the REF genes and set off against a calibrator (PC) \( \Delta \Delta Cq \) method. By subtracting \( \Delta Cq \) from the total number of cycles [40] it was ensured that normalized gene expression is proportional to the corresponding mRNA expression levels. This method facilitates interpretation of data and clinicopathological correlations. The various calculation steps are summarized in the following formula: 40−\( \Delta \Delta Cq \) (MG)S = 40 – ([Cq(MG) S – meanCq(REF)S] – [Cq(MG)pc – meanCq(REF)pc]).

Finally, the individual biomarker dynamics upon ICI treatment was determined by subtracting post-treatment expression values from pre-treatment expression values (\( \Delta \) expression).

Objective cut-off points for high and low expression were determined by the median expression of each marker.

### Statistical analysis

The primary endpoint was efficacy of pembrolizumab given 1\textsuperscript{st} line in terms of progression-free survival (PFS). Secondary endpoints were OS from start of 1\textsuperscript{st} line therapy and best response. Markers were evaluated for their predictive value for these endpoints.

Tumor responses were assessed by thoracic computed tomography (CT) and abdominal ultrasound or other clinically appropriate abdominal imaging technique at least every 3 months or upon clinical deterioration.

Tumor responses were evaluated according to the RECIST (Response Evaluation Criteria in Solid Tumors) version 1.1 (24). Complete response (CR) was defined as disappearance of all target and non-target lesions. Partial response (PR) was defined as \( \geq 30\% \) reduction in size in target lesions or disappearance of \( \geq 1 \) non-target lesions. Stable disease (SD) was defined as \( < 30\% \) decrease or \( < 20\% \) increase in size of target lesions or the persistence of \( \geq 1 \) non-target lesions. Progressive disease (PD) was defined as \( \geq 20\% \) increase in size or the appearance of new non-target lesions and/or progression of existing non-target lesions. The ORR was defined as the best response recorded from the start of treatment until disease progression or recurrence, confirmed by repeat assessments performed no less than four weeks after the first timepoint when criteria for response had been reached. Disease control rate was defined as percentage of patients with CR plus PR plus SD. Overall survival was recorded from the first day of 1\textsuperscript{st} line palliative treatment with pembrolizumab to the date of death or last follow-up. PFS was defined as the interval from the first day of 1\textsuperscript{st} line treatment to the first sign of disease progression or death whichever occurred first. Subsequent therapies were documented.

Descriptive data are presented as median and 95% confidence interval, categorical variables are presented using numbers and frequencies. PFS and OS are presented as median and 95% confidence interval (CI), and times to events were determined using the Kaplan-Meier method and compared with the log-rank test. Cox proportional hazards models were used to evaluate the influence of different patient factors. Statistical results were calculated using SPSS® (IBM; version 23). A P value <0.05 was considered statistically significant.

### Results

#### Patient population

After excluding 7 patients treated with pembrolizumab 1\textsuperscript{st} line at our center (4 patients with insufficient blood samples for and after start of ICI treatment and 3 patients with insufficient follow-up data), 45 patients met the inclusion criteria. The baseline demographic data and tumor characteristics are listed in Table 1. The median age was 68 years (range, 49–82 years), and 57.8\% of the patients were male. More than half of the patients had an Eastern Cooperative Oncology Group performance status (ECOG-
PS) of 0 (58.1%). PD-L1 immunohistochemistry data were available for all patients. All patients had a TPS score of ≥50%. Of those 48.9% and 51.1% presented with a TPS score of ≥50% and <75% or ≥75%, respectively.

### Outcome of the whole cohort

After a median follow-up of 27.4 months an ORR to 1st line therapy was observed in 66.7% of patients with a median duration of response (DOR) of 34.1 months (95% CI: 20.6–47.6). Disease control rate was 68.9% with 22% showing a progressive disease (PD) (Table S1). After a median number of 11 cycles of pembrolizumab (range, 2–38) the median PFS was 13.2 months (95% CI: 3.4–23.1) with 6-, 12- and 24-month PFS rates of 66.7%, 50.4% and 44.4%, respectively. Six patients (13.3%) were still on treatment. From the start of ICI the median OS was 29 months (95% CI: not reached) with 12- and 24-month survival rates of 65.7% and 59.4%, respectively (Figure 2).

In addition, clinical subgroups were tested for predictive value in terms of PFS or OS. Beside histologic type of NSCLC (adenocarcinoma vs. squamous cell carcinoma or NOS) which determines a significant difference in PFS (P=0.033) and a trend for OS (P=0.061) none of the other parameters were of significant predictive value (Table 2). While type of histology was a significant parameter for PFS in the univariate cox-regression analysis it did not remain significant in multivariate analysis (data not shown).

### Table 1 Demographics

| Parameters | N (%) |
|------------|-------|
| Gender     |       |
| Male       | 26 (57.8) |
| Female     | 19 (42.2) |
| Age        |       |
| <65 years  | 11 (24.4) |
| ≥65 years  | 34 (75.6) |
| Histology  |       |
| Adeno-ca   | 28 (62.2) |
| Squamous cell ca | 13 (28.9) |
| NOS        | 4 (8.9) |
| Stage at start of ICI |       |
| Stage IVA  | 11 (24.4) |
| Stage IVB  | 34 (75.6) |

| ≥75%       | 23 (51.1) |

NOS, not other specified; ICI, immune-checkpoint inhibitor; ECOG-PS, Eastern Cooperative Oncology Group performance status; TPS, tumor proportion score.

### Figure 2 Kaplan-Meier curves of the whole cohort. (A) PFS, (B) OS. ICI, immune-checkpoint inhibitor; PFS, progression-free survival; OS, overall survival.
Blood-based gene expression before start of ICI treatment and survival

To identify predictive peripheral blood biomarkers for pembrolizumab treatment, we examined PD-1, PD-L1, CTLA-4, CD3 and CD8 before treatment. Relative gene expressions divided by their median in low and high expression revealed no significant difference for ORR, PFS or OS in log rank test (Table 3 and Table S2). Though not statistically significant, it was interesting to see, that PD-L1 TPS scores (<75% vs. ≥75%) from the tumor tissue and PD-L1 expression (low versus high expression by median) from the LB revealed similar mPFS rates and Kaplan-Meier curves; the corresponding mPFS rates were 6.9 vs. 17.8 months (TPS score P=0.401) and 6.4 and 17.8 months (gene expression P=0.262) for low and high expressers, respectively (Figure 3). Comparing mRNA markers with general blood/serum marker (leucocytes, neutrophils, CRP or LDH) indicated that the quantitative assessment by molecular analysis of CD3, CD8, PD-1, PD-L1 and CTLA4 identifies a subset of immune cells, which does not relate to total amount of less characterized immune cell types. While no correlation of the mRNA levels of immune markers could be found with LDH, there were some modest positive Spearman correlations (r=0.26 to r=0.38) when comparing mRNA markers with lymphocyte counts, which did not reach statistical significance (P=0.07 to P=0.21) (data not shown).

Difference of blood-based gene expression before and after start of ICI treatment and survival

Next, we performed measurements of the five above
Table 3 PFS and OS of mRNA-based gene expression from whole blood—expressions before start of therapy

| Parameters | PFS | OS |
|------------|-----|----|
|            | Median, months | P value | Median, months | P value |
| CD3        |     |     |     |     |     |
| Low        | 11.2 | 0.981 | NR          |
| High       | 13.2 | 0.960 |
| CD8        |     |     |     |     |     |
| Low        | 6.4  | 0.730 | 29.0    |
| High       | 13.2 | 0.870 | NR       |
| CTLA-4     |     |     |     |     |     |
| Low        | 11.2 | 0.638 | 29.0    |
| High       | 13.2 | 0.553 |

mentioned biomarkers after start of ICI treatments. Pre- and post ICI mRNA expressions were comparable due to 40–ΔCt values, were all in the same range and therefore, highly comparable. In addition, to evaluate a dynamic change, we categorized patients for every marker into decreased expression (Δ ≤0) and increased expression (Δ >0) post treatment groups.

ORR and PFS were significantly improved by patients with increased whole blood expression of CD3 and CD8 within 3 weeks after start of pembrolizumab therapy (Table 4 and Table S3). Interindividual CD3 and CD8 changes from baseline in association to the median PFS...
are shown in Figure S1. Especially, CD8 revealed to be a good predictive discriminator with mPFS rates of 40.0 months (increase) versus 4.7 months (decrease) (P<0.001) (Figure 4). The same strong predictive value was observed for OS where the intra-individual change CD8 exhibited mOS rates of NR vs. 11.1 months (P<0.001) Similarly, intraindividual change in CD 3 expression was of predictive value in terms of OS with mOS rates of NR vs. 12.7 months for increase versus decrease of this marker, respectively (Figure 5). In contrast, changes of PD-1 and PD-L1 were not predictive, neither for PFS nor OS (Table 4).

In this study we could demonstrate that intraindividual dynamic changes in mRNA expressions of CD3 and CD8 occur after the first application of pembrolizumab in therapy naïve NSCLC patients and are predictive for better PFS and OS. CD8 expressing cells being positive for PD-1 (CD8^+PD-1^+) are a subpopulation of T lymphocytes which are exhausted in tumors where the PD-1 pathway leads to a tumor immune escape (25). The mode of action of immune-checkpoint inhibitors is the blockade of the PD-1 pathway leading to a reinvigoration of T cells with proliferation of CD8^+PD-1^+ T cells (16). The proliferation of those T cells recovers their functions and leads to tumor infiltration (26). In melanoma it could be shown that these CD8^+PD-1^+cells were functional cytotoxic T cells targeting cancer and their increase after ICI treatment had been associated with tumor response (27).

In line with our findings are analyses in the peripheral blood of NSCLC patients responding to PD-1 directed ICI therapy where an association with early proliferation of CD8^+PD-1^+ T cells could be detected. A study by Kamphorst et al. described that those dynamic changes occurred in Ki-67^+CD8^+PD-1^+ T cells from the peripheral blood of 29 NSCLC patients before and after start of ICI

### Table 4

| Parameters | mPFS      | mOS      |

therapy (17). An increase after the first or second course of treatment at a 2–6 weeks’ time interval was associated with better clinical response. Ki-67⁺CD8⁺PD-1⁺ T cells have also been measured in another cohort of 79 NSCLC patients before and during ICI treatment (18). An increase in those cells in the peripheral blood at the first week of PD-1 directed therapy was also associated with radiological tumor response. In addition, those patients had a favorable outcome in terms of PFS and OS. Very recently, Yamauchi et al. described CX3CR1 as another marker on CD8⁺ T cells being involved in response to a PD-1 directed therapy in NSCLC patients (20). After proof of principle in mice the peripheral blood of 36 human patients was studied for dynamic changes of this T cell marker. In line with the tumor-bearing mice results an increase in CXCR1⁺CD8⁺ T cells after start of ICI was associated with response and a clinically relevant better PFS. In summary, the increase in CD8 mRNA detected in the peripheral blood of NSCLC patients responding to pembrolizumab in our cohort supports findings of basic research studies and might be an easy to obtain surrogate marker of proliferating CD8⁺PD-1⁺ T cells.

Likewise, a dynamic increase in expression of CD3 was associated with a favourable outcome in terms of PFS. The marker measured by us was CD3Z, a sequence being part of the T-cell receptor (TCR) (28). Activation of the host immune response against tumor cells includes the recognition of neoantigens by proliferating TCRs (16,29). Thus, changes in the clonality or repertoire of the TCR might predict response to ICI (30). In a study by Han et al., the TCR repertoire diversity of CD8⁺PD-1⁺ T cells in the peripheral blood was measured before and 4–6 weeks after ICI therapy in 40 NSCLC patients (16). Interestingly, they could show that both an increased clonality as well as

Δ, change in expression before and after start of immune-checkpoint inhibitor. OS, overall survival; PD-1, programmed cell death protein 1; PD-L1, programmed cell death-ligand 1; CTLA-4, cytotoxic T-lymphocyte-associated protein 4.

Figure 5 Kaplan-Meier curves of OS according to dynamic changes: (A) Δ CD3, (B) Δ CD8, and (C) Δ CTLA-4. Δ, change in expression before and after start of immune-checkpoint inhibitor. OS, overall survival; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; ICI, immune-checkpoint inhibitor.

To our knowledge there are only few reports published so far on mRNA expressions of immune-related genes from whole blood samples obtained from peripheral blood before and during start of pembrolizumab treatment in NSCLC. Till now, attention of basic research engaged in diversity of the TCR were associated with better response and longer survival. These data underline that dynamic changes in a subset of CD8 and CD3 cells occur very early after start of an ICI directed therapy and can be detected via circulating mRNA in the blood.
liquid biopsy is mainly directed on CD8+ T cells which was reported above and needs laborious cell sorting techniques. In contrast, mRNA seems to be robust and gene expressions are quite easily to measure (31). In a study by Yang et al. published very recently, mRNA expression in blood plasma was analyzed in 33 patients before and two months after initiation of ICI therapy in NSCLC (32). They could show that increased expression of PD-L1 mRNA (≥2.04 fold-change) was correlated as well with clinical response and better outcomes in terms of OS and PFS. Their data are in line with our results were dynamic changes of PD-L1 and PD-1 occurred during ICI treatment. While our data point the same direction, with higher expressions indicating a good prognosis, our data were not statistically significant in this part of our analyses. However, in contrast to the study by Yang et al. we measured dynamic changes after three weeks which might be the cause of underscoring the effect of increase of PD-L1 expression over time. In addition, patients in our cohort had to have a tissue PD-L1 TPS of ≥50% to be eligible for pembrolizumab treatment. As PD-L1 ≥50% measured by IHC is described as a marker of good response and outcome, all our patients were already in this group and dynamic changes might not be of such relevance as in the cohort of Yang et al. where the whole range of the PD-L1 TPS was included. Interestingly, patients in our study presenting with a baseline PD-L1 mRNA expression above the median had increased survival data in terms of PFS in contrast to patients with lower expressions with median PFS of 17.8 and 6.4 months, respectively. These data were highly comparable to the immunohistochemical tissue data of the same patients with a TPS score dichotomized into ≥75% vs. <75% with median PFS rates of 17.8 and 6.9 months, respectively. This indirect comparison may be a hint of the robustness and evaluability of mRNA measured in whole blood samples.

Our study suggests that changes in CD8 mRNA expression immediately after the first course of an ICI may easily identify patients with a high chance of good clinical response to this ICI monotherapy. In the KEYNOTE-24 trial a 6-months PFS rate of 62.1% was described for the pembrolizumab arm (7). This result is very comparable with the 66.7% of patients in our cohort remaining on treatment after 6 months. In reverse, these data indicate that about one third of patients will have clinical progression within the first 6 months of treatment. Those non-responsive patients might be treated by combining ICI with platinum-based chemotherapy. Based on our data the switch from ICI monotherapy to ICI-chemotherapy could be initiated as early as the second course of ICI. Data from the KEYNOTE 189 and KEYNOTE 407 showed that a combination therapy is superior to a chemotherapy only regimen in terms of PFS and OS in squamous and non-squamous carcinoma, respectively (33,34). After reaching both endpoints pembrolizumab plus platinum-based chemotherapy regimen are approved for squamous and non-squamous NSCLC patients regardless of the PD-L1 TPS status. In addition, a combination therapy including platinum-based combination therapy in combination with a PD-1 (nivolumab) and a CTLA-4 directed antibody (ipilimumab) were also approved in this setting as the registrational phase III trial 9LA had been positive for its primary endpoint OS (35). However, whether a rapid change after one cycle of therapy from pembrolizumab monotherapy to ICI plus chemotherapy is associated with clinical benefit has to be shown as there is not even a head-to-head comparison between ICI based mono- and ICI plus chemotherapy.

### Table 6 Univariate and multivariate analyses on OS in Δ gene expression

| Parameters                        | OS            | Univariate analysis | Multivariate analysis |
|-----------------------------------|---------------|---------------------|-----------------------|
|                                   |               | HR                  | 95% CI                | P value   | HR                  | 95% CI                | P value   |
| Δ CD3 (increase vs. decrease)     | 2.920         | 1.124–7.585         | 0.028                 | 0.467     | 0.109–1.996         | 0.302                 |
| Δ CD8 (increase vs. decrease)     | 5.010         | 1.740–14.420        | 0.003                 | 9.747     | 1.900–50.013        | 0.006                 |
| Δ CTLA-4 (increase vs. decrease)  | 2.181         | 0.874–5.442         | 0.095                 |           |                      |                       |
| Δ PD-1 (increase vs. decrease)    | 1.582         | 0.636–3.932         | 0.323                 |           |                      |                       |
| Δ PD-L1 (increase vs. decrease)   | 1.514         | 0.613–3.740         | 0.369                 |           |                      |                       |

Δ, change in expression before and after start of immune-checkpoint inhibitor. OS, overall survival; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; PD-1, programmed cell death protein 1; PD-L1, programmed cell death-ligand 1.
chemotherapy combination-regimen to date.

Limitations of this study include the retrospective design, the lack of an independent validation cohort, and the small sample size. Another important limitation is the fact that the mRNA was measured from whole blood and therefore, it is not clear from which exact subtypes of immune cells it may have been released. Though mRNA seems to be more robust in blood as originally adopted, and ct-values could be consistently repeated, independent cohorts are necessary to confirm these results. Furthermore, we do not know whether there are dynamic changes also at the time of progression of patients initially responded to pembrolizumab. This will be part of a further research project. At least, patients included in this study had to have two time points in a 3-weeks interval where blood was taken for mRNA analyses. All patients with just one liquid biopsy probe taken before ICI treatment were excluded. Therefore, there might be a lack in terms of missing poor performing individuals after one cycle of pembrolizumab. However, as our 6-months PFS data are comparable with the KEYNOTE-24 study a relevant bias might be excluded.

In conclusion, in this study we demonstrate that mRNA expression of immune-related genes can be measured from whole blood samples during ICI and dynamic changes with increase of CD8, CD3 and CTLA-4 mRNA expression three weeks after start of pembrolizumab were associated with favorable outcome in terms of PFS and OS. Especially, a dynamic change in CD8 expression with increase after the first application of ICI was an independently predictive for better PFS and OS. These results, if confirmed in a larger cohort, demonstrate a potential role for serial mRNA analyses of these markers as a new early indicator of clinical efficacy of ICI therapy. In particular, the dynamic changes in immune-related mRNA expressions could allow earlier prediction of clinical benefit compared with radiological imaging. Patients who do not respond to pembrolizumab monotherapy might thus be identified earlier, so that their therapy can then be modified earlier than before. Early escalation of such non-responsive patients for instance to chemo-ICI combination therapy might improve their outcomes significantly.

Acknowledgments

We thank all the patients who participated in this study. In addition, the authors want to thank Mrs. Ute Herbst for help with blood collection, Mrs. Alexandra Barhoumi for documentation of obtained blood samples and Mr. Maximilian Brueckl for help with the figures.

Funding: This research was funded by the W. Lutz Stiftung, Nuremberg Germany by an unrestricted grant to WM Brueckl and JH Ficker.
