ABSTRACT

We use very deep near-infrared photometry of the Hubble Deep Field South taken with ISAAC/VLT to identify a population of high redshift galaxies with rest-frame optical colors similar to those of nearby galaxies. The galaxies are chosen by their infrared colors $J_s-K_s > 2.3$, aimed at selecting galaxies with redshifts above 2. When applied to our dataset, we find 14 galaxies with $K_s < 22.5$, corresponding to a surface density of $3 \pm 0.8$ arcmin$^{-2}$. The photometric redshifts all lie above 1.9, with a median of 2.6 and a rms of 0.7. The spectral energy distributions of these galaxies show a wide range: one is very blue in the rest-frame UV, and satisfies the normal Lyman-break criteria for high redshift, star-forming galaxies. Others are quite red throughout the observed spectral range, and are extremely faint in the optical, with a median $V = 26.6$. Hence these galaxies would not be included in photometric samples based on optical ground-based data, and spectroscopic follow-up is difficult. The spectral energy distributions often show a prominent break, identified as the Balmer break or 4000 Å break. The median age is 1 Gyr when fit with a constant star formation model with dust, or 0.7 Gyr when fit with a single burst model. Although significantly younger ages cannot be excluded when a larger range of models is allowed, the results indicate that these galaxies are among the oldest at these redshifts. The volume density to $K_s = 22.5$ is half that of Lyman-break galaxies at $z \approx 3$. Since the mass-to-light ratios of the red galaxies are likely to be higher, the stellar mass density is inferred to be comparable to that of Lyman-break galaxies. These red galaxies may be the descendants of galaxies which started to form stars at very high redshifts, and they may evolve into the most massive galaxies at low redshift.

Subject headings: galaxies: evolution, galaxies: high redshift

1. INTRODUCTION

One of the most effective ways to find high redshift galaxies is the Lyman-break selection technique (Steidel & Hamilton 1993, Steidel et al. 1996a,b). This selection method relies on the strong break in the rest-frame far-UV spectrum of strongly star-forming galaxies. The density of bright Lyman-break galaxies at $z \approx 3$ is comparable to that of $L_s$ galaxies nearby, and this population is a major constituent of the high redshift universe. Other selection techniques based on sub-mm, or X-ray emission have yielded complementary samples, with generally little overlap, and much smaller number densities (e.g., Smail et al., 2002a, Barger et al., 2002). The sub-mm galaxies may, however, contribute significantly to the overall star formation rate.

All of these techniques select galaxies which are very different from normal galaxies in the present-day universe, the light of which is dominated by rather evolved stars. Normal galaxies are too large, and too faint in the far-UV to be selected as Lyman-break galaxies at $z \approx 3$ (e.g., Giavalisco et al. 1996). This raises the question of whether we may still be missing a significant population of galaxies at high redshift.

This issue can be addressed by means of very deep near-infrared (NIR) imaging. A normal $L_s$ galaxy would have a $K$ band magnitude of $\approx 23$ when redshifted to $z = 3$, out of reach of 4m class telescopes. The development of large telescopes with good image quality, and large NIR detectors has made it possible to achieve the depth necessary to select high redshift galaxies by their observed infrared light.

In this paper we present results obtained at the VLT on the Hubble Deep Field South (HDF-S, Williams et al. 2000, Casertano et al. 2000), as part of the FIREs project (Franx et al. 2000). We imaged the WFPC2 field of the HDF-S with ISAAC in 3 passbands ($J_s, H, K_s$), with a total integration time of 103 hours. The data processing and results are discussed in Labbé et al. (2003). The first results based on a subset of the data were presented by Rudnick et al. (2001). All magnitudes given here are in the Johnson system unless noted otherwise.

2. INFRARED SELECTION OF HIGH REDSHIFT GALAXIES

We consider the selection of galaxies which are not dominated by an unobscured starburst in their rest-frame UV-optical light. We wish to define a simple photometric criterion which can select such galaxies, similar to the U-dropout criterion to select Ly-break galaxies. Unfortunately, the rest-frame optical spectra of optically red galaxies do not contain any feature as prominent as the Lyman break of star-forming galaxies. However, we can use the Balmer break and 4000 Å break to select high redshift galaxies. The lower strength of this feature implies that we need to obtain very deep photometry. Since the breaks shift into the $J_s$ band at $z \approx 2$, a red $J_s-K_s$ color is a
simple and effective criterion. This is illustrated in Fig. 1, where we show tracks of $J_s - K_s$ versus redshift for model spectra taken from Bruzual & Charlot (1996). If we impose a criterion $J_s - K_s > 2.3$, we select galaxies with $z > 2$, even if we allow for dust extinction.

Exceptions will occur, obviously. Some of the lower redshift EROs have $J - K > 2.3$ (e.g., Smail et al. 2002b), but their surface density is low ($\approx 0.2$ arcmin$^{-2}$). Hall et al. (2001) selected 4 galaxies with $J - K > 2.5$, and found photometric redshifts $z \geq 2$, in agreement with our simple tracks.

Figure 2 shows the $J_s - K_s$ versus $I - K_s$ colors of the galaxies in the HDF-S with $K_s < 22.5$. We find 14 galaxies down to this limit with $J_s - K_s > 2.3$. Since our effective area is 4.7 arcmin$^2$, this implies a surface density of $3 \pm 0.8$ galaxies arcmin$^{-2}$, which is seven times that of bright Lyman-break galaxies around $z = 3$ selected by the ground-based U-dropout technique (Steidel et al. 1996a). The redshift distributions of the two samples are significantly different, however, and the volume densities are more comparable as we shall see below.

The full spectral energy distributions of a subset of the galaxies are shown in Fig. 3. The majority of the galaxies show a distinct break in the NIR, which we interpret as the Balmer/4000 Å break. The galaxies have a wide range in optical-NIR colors (Figs. 2 and 3). We find 5 extremely red galaxies with $J_s - K_s > 3$, and 4 of these are red in all colors. Their colors are rather similar to the galaxies found by Dickinson et al. (2000), and Im et al. (2002).

3. REDSHIFTS AND DENSITY

Most of the galaxies are extremely faint in the optical, with a median V band magnitude of 26.6. As a result, it is very difficult to measure redshifts spectroscopically with current instrumentation, and we have to rely on photometric redshifts instead. Fortunately, the spectral breaks which many of the galaxies show in the NIR help to derive the photometric redshifts.

We have used the photometric redshifts published by Labbé et al. (2003), based on algorithm developed by Rudnick et al. (2001, 2003). The SED is fit with a linear combination of templates based on observed spectra of nearby galaxies. It gives good agreement with the spectroscopic redshifts available in the HDF-South, with an average $|\Delta z|/(1+z) = 0.08$. We verified that the derived density remains the same within the errors if another method is used ("hyperz" by Bolzonella, Miralles, & Pello 2000). Spectroscopic confirmation of the photometric redshifts is urgently needed, obviously.

The photometric redshifts of the red sample with $K_s < 22.5$ range from 1.92 to 4.26, with a median of 2.6, and an rms of 0.7. The volume density is derived in the interval $2 < z < 3.5$, identical to that of U-dropouts selected from WFPC2 imaging. Eleven galaxies lie in this redshift range, resulting in a volume density of 0.0014 $\pm$ 0.0004 h$^3$ Mpc$^{-3}$. Errors in the photometric redshifts are likely to reduce the measured volume density, as they will push galaxies outside the sampled volume. The derived volume density is half that of Lyman-break galaxies at $z \approx 3$ to $R_{AB} = 25.5$ (Steidel et al. 1999). Hence the contribution of this sample to the overall density is substantial. The variations due to large scale structure are the main source of uncertainty. We note, for example, that the number of galaxies with red $I - H$ color is much higher in HDF-South than in HDF-North (Labbé et al. 2003). On the other hand, our second deep field of 5x5 arcmin contains a similar surface density of $J_s - K_s$ selected galaxies as HDF-South to $K_s = 21$ (van Dokkum et al., 2003). Surveys over larger areas are needed to establish how typical these areas are, and are now in progress.

4. COMPARISON WITH LYMAN-BREAK SELECTED SAMPLES

The large volume density derived above raises the question how the red galaxies are related to the "classical" Lyman-break
galaxies (Steidel et al. 1996a,b). In principle, a galaxy can be both red in $J_s - K_s$ and be a Lyman-break. In order to compare the two samples we select galaxies in the HDF-South with $2 < z < 4$ and $K_s < 22.5$, and apply the criteria for U-droppouts as defined by Steidel et al. (1996b). Surprisingly, the two samples are nearly disjoint. Only 1 galaxy satisfies both criteria. Many of the $J_s - K_s$ galaxies fail to satisfy the U-drop criteria because they are too faint in the $B$ or $V$ band. Even with HDF-South quality data, it is not possible to establish whether they have a prominent break between $U$ and $B$. Conversely, the median $J_s - K_s$ color of the U-dropout galaxies is very blue: we find a median of 1.6, identical to that found by Shapley et al. (2001) for a ground-based selected sample.

The disjoint nature of the two populations is illustrated in Fig. 4., where we show the $R_{AB} - K_s$ color versus $K_s$ magnitude. The synthetic $R_{AB}$ magnitude was derived by averaging the $V_{AB}$ and $I_{AB}$ magnitudes. Galaxies of different types are indicated by different symbols. The U-dropout galaxies are blue and follow a well defined color-magnitude relation, as found earlier by Papovich et al. (2001). The $J_s - K_s$ selected galaxies show a very large range in color, $4 \leq R_{AB} - K_s \leq 7$.

The relative contributions of the two types of galaxies to the total observed $K_s$ band light is similar to their relative number densities: The galaxies with $J_s - K_s > 2.3$ contribute 24% to the total observed $K_s$ band light from galaxies with $2 < z < 4$ and $K_s < 22.5$, and the Lyman-breaks contribute 55%. The relative contribution of the $J_s - K_s$ selected galaxies to the stellar mass is expected to be higher, as the red colors indicate higher mass-to-light ratios. Fig 4. shows the track of constant stellar mass for a single stellar population observed at $z = 3.0$ for ages between 0.1 and 2 Gyr, based on models by Bruzual & Charlot (1996). If we use this track to correct the relative luminosities to relative masses, we derive that the $J_s - K_s$ selected galaxies contribute 43% to the stellar mass. This fraction increases further if the sample were mass selected. Hence, the population of red galaxies is a significant component at the high mass end.

Fig. 4. can also be used to analyze the selection effects of most of the ground-based spectroscopic surveys. Usually, spectroscopic samples of U-dropout galaxies are selected to have $R_{AB} < 25.5$, indicated by the continuous line. All but one of the $J_s - K_s$ galaxies have $R_{AB} > 25.5$, and hence most would be excluded. The $R$ band selection criterion is effective in selecting galaxies with strong, unobscured star formation, but misses a significant population of galaxies with redder colors. Lines of constant mass run nearly perpendicular to the $R$ band selection criterion: if we select galaxies in the optical we miss red galaxies over a wide range of masses, and up to the highest masses. Follow-up studies of NIR selected samples are necessary to obtain a full census of the high redshift universe, unfortunately, such studies are very hard.

5. STELLAR POPULATIONS

The $J_s - K_s$ selected galaxies have much redder colors than most Lyman-breaks, which can result from older ages, more reddening, or a combination of effects. Furthermore, emission lines can contribute to some of the passbands and influence the colors. Here we attempt to understand the stellar populations of the galaxies better by analyzing the colors and SED’s. For the moment, we ignore the effects of emission lines as they are likely small (e.g., Shapley et al. 2001, van Dokkum et al. 2003, van Dokkum et al. in preparation).

The breaks in the SED’s of many of the galaxies can be used to put lower limits on the ages. Color-color diagrams using the $I - J_s$, $J_s - H$, and $H - K_s$ colors show that 9 out of 14 galaxies have breaks which cannot be explained by reddened models of stellar populations with constant star formation and young age ($\leq 100$ Myr). Generally, models with ages $> 300$ Myr and higher can produce strong enough breaks to explain the features, in combination with dust.

We can use the full SED to fit models of stellar populations. We used models by Bruzual & Charlot (1996), with a Calzetti et al. (2000) reddening law. As is well known, it is very hard to disentangle the effects of age and dust in such fits (e.g., Pa-
povich et al. 2001, Shapley et al. 2001). However, 11 out of 14 of the galaxies are badly fit by models with very young populations (age ≤100 Myr) and very large reddening. The χ²-test rules out these fits at the 95% confidence level. Unreddened single age bursts can be ruled out in the same way for 12 galaxies. Models with constant star formation produce a median age of 1 Gyr and a median reddening of E(B-V)= 0.5. Both the age and the reddening are about 3 times higher than the median values for Lyman-breaks at $z=3$, 0.3 Gyr and 0.16, respectively (Shapley et al. 2001). Two of the very red galaxies are best fit by single burst models without dust, as determined from the χ². These models have an age of 3.5 Gyr. If all galaxies are fit with a single age population, the median age derived is 0.7 Gyr, with a large spread.

As shown by Papovich et al (2001) and Shapley et al (2001), the derived ages and reddening can vary by a factor of 2 if other star formation histories, IMF's, or reddening laws are used. The relative ages of galaxies are more stable, however. Our models are identical to those used by Shapley et al (2001), hence the age comparison should be more secure. Again, follow-up studies are required to constrain the stellar populations better. NIR spectroscopy will be essential to estimate star formation rates and reddening from emission lines.

6. DISCUSSION

The results presented here raise many questions. Obviously, follow-up work is required to verify how typical the HDF-South is. Deep NIR-imaging over a wide area is needed to obtain a robust estimate of the surface density. Furthermore, it is critical to determine the spectroscopic redshifts of at least some of these sources. The first spectroscopic confirmation of galaxies selected in this way is presented in a companion paper (van Dokkum et al., 2003). The most pressing question of all, however, concerns the nature, formation and evolution of these red galaxies, and their relation to other high redshift galaxies, especially to the well-studied Lyman-breaks.

The simplest explanation would be that the red galaxies are directly related to Lyman-break galaxies. They may be viewed along dusty lines of sight, or during intermittent epochs of low star formation. If such a direct relation would hold, one would expect that both samples have a similar distribution on the sky, similar sizes, and similar clustering. The first results by Daddi et al. (2003) imply that the clustering of high redshift galaxies increases rapidly with redder $J−K_s$ colors. If confirmed by spectroscopy and larger area surveys, this would be inconsistent with this very simple scenario.

Alternatively, the red galaxies could be a population distinct from the $z≈3$ Lyman-breaks. They may have been Lyman-breaks at higher redshifts, and have become redder because of a decline in the star formation, an increase in age, and an increase of metallicity, and thereby dust. All three factors are expected to play a role in realistic galaxy evolution models. In this context, it is interesting to note that models of observed Lyman-break galaxies indicate that such red descendants must exist, as the ages of the stellar populations are generally much younger than the age of the universe at the redshift of the galaxies (e.g., Papovich et al., 2001, Ferguson et al. 2002). Unless these galaxies evolve in unexpected ways, one must see older, and relatively red “remnants”.

In the nearby universe, the reddest galaxies are generally the most massive, with the highest ages, metallicity, and correlation length. It is possible that such a relation already existed in the early universe. The red galaxies found here would be the descendants of galaxies which started to form stars very early, and would be related to more massive halos than those of the young Lyman-break galaxies at $z=3$. In this case their spatial densities are expected to be higher, and their correlation length to be enhanced, as found by Daddi et al. (2003). Work is in progress to test these predictions further. Unfortunately, the physical processes which determine the appearance of high redshift galaxies are not well understood, e.g., why are many strongly star-forming galaxies at $z = 3$ UV-bright, and most counterparts at low redshift strongly reddened? In the absence of a good understanding of the high redshift galaxies, and of the feedback processes which may regulate star formation, it is not clear whether a simple extrapolation of the phenomena at low redshift to high redshift is valid.

Finally, caution is required, and we should leave open the possibility that we do not understand the nature of these sources yet. We note that similar objects have been found by others (e.g., Dickinson et al. 2000, Hall et al. 2001, Totani et al. 2001, Im et al. 2002). Although we have obtained spectroscopy for a limited sample (van Dokkum et al., 2003), this is only feasible for a small fraction of the sample at this moment. Near-infrared spectroscopy is very urgently needed to confirm that the colors which are observed are not dominated by emission lines, although it appears quite unlikely that many galaxies would be affected greatly.

The comments of the referees helped to improve the paper. We thank the staff at ESO for their hard work to take these data and make them available. This research was supported by grants from the Netherlands Foundation for Research (NWO), the Leids Kerkhoven-Bosscha Fonds, a NASA SIRTF fellowship, and the Lorentz Center.
