(Dated: June 13, 2008)

Density functional studies of 26K superconducting LaFeAs(O,F) are reported. We find a low carrier density, high density of states, $N(E_F)$ and modest phonon frequencies relative to $T_c$. The high $N(E_F)$ leads to proximity to itinerant magnetism, with competing ferromagnetic and antiferromagnetic fluctuations and the balance between these controlled by doping level. Thus LaFeAs(O,F) is in a unique class of high $T_c$ superconductors: high $N(E_F)$ ionic metals near magnetism.

PACS numbers: 74.25.Jb, 74.25.Kc, 74.70.Dd, 71.18.+y

Understanding the interplay between superconductivity and spin fluctuations especially near magnetic phases is an important challenge. The discovery of a new family of layered superconductors containing the magnetic elements Fe and Ni and critical temperatures up to $T_c = 26$K specifically LaOFeP ($T_c = 4$K, and $\sim 7$K with F doping)\textsuperscript{1,2} and LaONiP ($T_c = 3$K)\textsuperscript{3} and F doped LaOFeAs with $T_c = 26$K (Ref. 4) raises questions about the relationship between magnetism and superconductivity, the origin of the remarkably high $T_c$, and the chemical and structural parameters that can be used to tune the properties. Here we show that LaOFeAs is in fact close to magnetism, with competing ferromagnetic and antiferromagnetic fluctuations, with the balance controlled by doping. Furthermore, we identify La(O,F)FeAs as a nearly 2D, low carrier density metal, with modest phonon frequencies relative to $T_c$, and high density of states.

The crystal structure is layered with apparently distinct LaO and transition metal pnictide layers. (see e.g. Ref. 4) Importantly, it forms with a wide range of rare earths and pnictogens, with the transition elements Mn, Fe, Co, Ni, Cu and Ru, and additionally, related fluorides and chalcogenides are known\textsuperscript{2,3,12} It may be that there are other superconducting compositions that remain to be discovered in this family.

Our calculations were done using the local spin density approximation (L(S)DA) and the generalized gradient approximation (GGA) of Perdew, Burke and Ernzerhof (PBE).\textsuperscript{13} We used the linearized augmented plane wave (LAPW) method with tested basis sets and zone samplings for the electronic structure.\textsuperscript{14} Two independent LAPW codes were used - an in-house code, and the WIEN2K package.\textsuperscript{15} Transport properties were calculated using BoltzTraP.\textsuperscript{16} The phonon dispersions were obtained in linear response via the quantum espresso code\textsuperscript{17} using BoltzTraP.\textsuperscript{16} The phonon dispersions were obtained in linear response via the quantum espresso code

The electronic density of states (DOS) and band structure are shown in Figs. 1 and 2. The band structure is similar to that reported for LaFePO\textsuperscript{11}. Near the Fermi energy, $E_F$ it is well described as coming from 2D metallic sheets of Fe$^{2+}$ ions in an ionic matrix formed by the other atoms. There is a group of 12 bands between -5.5 eV (relative to $E_F$) and -2.1 eV. These come from O p and As p states, with the As p contribution concentrated above -3.2 eV. These As derived bands are hybridized with the Fe d states. The Fe d states account for the bands between -2.2 eV and 2 eV, with La derived states occurring at higher energy. This is the ordering expected from the Pauling electronegativities: 3.44 for O, 2.18 for As, 1.83 for Fe and 1.10 for La. While there is some hybridization between Fe and As, it is not strong and is comparable to oxides. Thus a separation of the structure into independent LaO and FeAs subunits is not justified from the point of view of electronic structure or bonding and so we write the chemical formulae in order of electronegativity. This ionic view is supported the similarity of the Fe d derived bands of LaFePO and LaFeAsO in spite of the chemical differences between P and As. This suggests that doping mechanisms other than replacement of O by F may be effective, i.e. on the La site (e.g. by Th) or the As site (e.g. by Te or Se). This may allow stabilization of the compound with a wider range of doping levels than can be achieved using the O site, perhaps leading to higher $T_c$.

Fe d states would normally split into a lower lying $e_g$ manifold and higher lying $t_{2g}$ states in an As tetrahedral crystal field. The gap between these would be at a $d$ electron count of 4 per Fe. However, this crystal field competes with the direct Fe-Fe interaction to yield
FIG. 1: (color online) LDA density of states and projections onto the LAPW spheres on a per formula unit both spins basis. Note that much of the As $p$ character will be outside the As sphere, reducing their apparent weight.

FIG. 2: (color online) Band structure of LaFeAsO around $E_F$ showing the effect As breathing along $z$ by $\delta z_{\text{As}}=0.04$ (0.035Å). The unshifted band structure is indicated by the solid black line, while the shift away (towards) the Fe is indicated by the blue dotted (green dashed) lines.

a more complicated band structure, with no clear gap at 4 electrons per Fe. Rather, the main feature is a pseudogap at an electron count of 6. The Fermi energy for $d^6$ Fe$^{2+}$ is at the pseudogap. While we do find sensitivity of the bands near $E_F$ to the As height as shown in Fig. 2, the PBE band structure with the PBE relaxed structure is very similar to the LDA band structure, including the details of the Fermi surface.

The Fermi surface (Fig. 3), has five sheets: two high velocity electron cylinders around the zone edge $M$-$A$ line, two lower velocity hole cylinders around the zone center, and an additional heavy 3-D hole pocket, which intersects and anti-crosses with the hole cylinders, and is centered at $Z$. The heavy 3-D pocket is derived from Fe $d_z$ states, which hybridize sufficiently with As $p$ and La orbitals to yield a 3D pocket. The remaining sheets of Fermi surface are nearly 2D. The electron cylinders are associated with in-plane Fe $d$ orbitals and have higher velocity and will make the larger contribution to the in-plane electrical conductivity. The Seebeck coefficients are positive because of the proximity to band edges in the hole bands: $S_{xx}=S_{yy}=6.8 \mu V/K$ and $S_{zz}=8.5 \mu V/K$, at 300K. However, for $N(E_F)$ and other quantities that depend on the density of states, such as spin-fluctuations, and electron-phonon coupling, the heavier hole pockets may be more important. Specifically, the three hole sheets together contribute 80% of $N(E_F)$ but only 31% of $N(E_F)v_z^2$. The average Fermi velocities are $0.81\times10^7$ cm/s (in-plane) and $0.34\times10^7$ cm/s ($c$-axis) for the hole sections and $2.39\times10^7$ cm/s (in-plane) and $0.35\times10^7$ cm/s ($c$-axis) for the electron sections. Including all sheets, $v_{xx}=v_{yy}=1.30\times10^7$ cm/s and $v_{zz}=0.34\times10^7$ cm/s. This yields a resistivity anisotropy of $\sim 15$ for isotropic scattering. We note that the DOS is rapidly changing near $E_F$ and therefore these quantities will be quite sensitive to the electron filling, structure and other details.

The volume enclosed by the two electron cylinders (equal to that enclosed by the hole sections) corresponds to 0.26 electrons per cell (0.13 per formula unit). $E_F$ lies just above a peak in the DOS, which leads to a rapidly decreasing DOS with energy. This peak is associated with a van Hove singularity from the 3D hole pocket, which becomes cylindrical as $E_F$ is lowered. The calculated value at $E_F$ is $N(E_F)=2.62$ eV$^{-1}$ per formula unit both spins. The corresponding bare susceptibility and specific heat coefficient are $\chi_0=8.5\times10^{-5}$ emu/mol and $\gamma_0=6.5$ mJ/mol K$^2$ Thus LaFeAsO is a low carrier concentration, high density of states superconductor. This is in contrast to the cuprates, which have high carrier concentration (near half filling with large Fermi surfaces) and lower density of states. Recent experimental data also indicates low carrier concentration. Electron
doping mainly shrinks the hole pockets, especially the 3D sheet, since these have higher mass than the electron surfaces. This leads to an increasingly 2D Fermi surface. Within Stoner theory a ferromagnetic instability occurs when $N I > 1$, with $N$ now on a per spin basis. Since the DOS near $E_F$ is close to pure Fe, it is characteristic to choose $I \sim 0.7 - 0.8$ eV, which would put $\text{LaFeAsO}$ very close to a magnetic instability.

Fixed spin moment calculations were done for the LaFeAsO, LaFePO and LaNiPO, and for LaFeAsO with O replaced by virtual atoms, $Z=7.9$ and $Z=8.1$ (to simulate doping). In the LDA $\text{LaFeAsO}$ is indeed on the borderline of a ferromagnetic instability and electron doping moves away from this instability. The ground state is an itinerant ferromagnet with a moment of 0.08 $\mu_B$/Fe. However, the small energies involved are below the precision of the calculation, so it may only be concluded that the material is on the borderline of ferromagnetism. This borderline behavior, where the energy is independent of magnetization, persists up to $\sim 0.2 \mu_B$/Fe. This is close to the value where the holes become fully polarized. This places stoichiometric $\text{LaFeAsO}$ near a ferromagnetic quantum critical point.

The experimental susceptibility $\chi(T)$ of undoped $\text{LaFeAsO}$ is weakly temperature dependent between 20K and 300K, with value $\sim 50 \times 10^{-5}$ emu/mol, and increases strongly at lower $T$. While the $T \chi(0)$ is not known, even taking the higher temperature value, the implied Stoner renormalization $(1 - N I)^{-1}$ from $\chi_{exp}/\chi_0$ is 6 and is probably significantly higher depending on the observed upturn below 20K. By comparison $\chi_{exp}/\chi_0$ is $\sim 5$ for MgCNi$_3$, $\sim 7$ for Sr$_2$RuO$_4$, and $\sim 9$ for Pd metal. Ferromagnetic spin fluctuations are strongly pair breaking for singlet superconductivity both in the $s$ channel favored by electron-phonon interactions, and in $d$ channels, such as in the high-$T_c$ cuprates. Thus such fluctuations would suppress $T_c$. However, it is conceivable that a sufficiently strong electron phonon interaction, which is needed to explain $T_c \sim 26$K in that scenario, could overcome the pair breaking effects of ferromagnetic fluctuations as was discussed for MgCNi$_3$. Turning to the F doped material, which is the actual superconducting phase, $\chi_{exp}$ is higher than for the stoichiometric material and increases as $T$ is reduced over the whole temperature range, rising to $\sim 200 \times 10^{-5}$ emu/mol at $T_c$. This is opposite to the trends with band filling in $N(E_F)$ and the fixed spin moment curve. The most simple explanation would be in terms of secondary phases. Another explanation is that the undoped compound is magnetically ordered. There is in fact a resistivity peak at $\sim 150$K and a minimum at $\sim 100$K, but $\chi(T)$ does not show strong changes at these temperatures.

We did calculations with an antiferromagnetic arrangement of the Fe spins in the square lattice. As for ferromagnetic alignment, we find a borderline instability, with stable moments in the virtual crystal calculations at lower electron count while the proximity to antiferromagnetism is reduced with increasing electron count. We also did calculations with small fields applied to the Fe LAPW spheres in both ferromagnetic and antiferromagnetic configurations. The resulting moments, defined by the magnitude of the spin polarization in each Fe LAPW sphere, are shown in Fig. 4 along with results of similar calculations for LaNiPO and LaFePO.

While ferromagnetism is initially favored, the antiferromagnetic response becomes larger for higher fields with a cross-over at an energy scale of 30K. Thus thermal fluctuations at higher temperature and perhaps quantum fluctuations would both favor antiferromagnetic fluctuations over ferromagnetism. This nearest neighbor antiferromagnetism is related to superexchange. Doping with electrons rapidly reduces the proximity to ferromagnetism. Furthermore, it should be emphasized that LaNiPO, which is also a superconductor has much lower susceptibility for both ferromagnetic and antiferromagnetic fluctuations.

The calculated phonon dispersions and density of states of LaFeAsO are shown in Fig. 5. The acoustic modes are not strongly anisotropic. In particular, there are no soft elastic constants associated with shear-
ing of the planes along the c-axis. The Debye temperature from the acoustic mode velocities is $\Theta_D=340K$ with an uncertainty of 10% due to sampling. Turning to the optic modes, the dispersions may be divided into two regions. Below $\sim 300 \text{ cm}^{-1}$ the dispersions are dominated by metal and As modes of mixed character, while the modes above $\sim 300 \text{ cm}^{-1}$ are strongly O derived. The phonon density of states shows three main peaks below 300 cm$^{-1}$. These are all of mixed metal and As character, and are a large peak centered at $\sim 100 \text{ cm}^{-1}$ and smaller peaks at $\sim 170 \text{ cm}^{-1}$ and $\sim 280 \text{ cm}^{-1}$.

The phosphides LaFePO and LaNiPO also superconduct, though with lower $T_c$. The band structures near $E_F$ of LaFeAsO and LaFePO (Ref. 11) are very similar. We find that LaFePO, like LaFeAsO is on the borderline of a ferromagnetic state in the LSDA. As expected from the different electron count, the electronic structure of LaNiPO is very different. Calculations yield large two dimensional Fermi surfaces and lower $N(E_F)$. With the assumption that the origin of superconductivity is the same in the Fe and Ni compounds, spin fluctuation mechanisms seem unlikely since these depend on a match between the $q$ dependent susceptibility and the Fermi surface, requiring different coincidences for the Fe and Ni compounds. One scenario would be that there are strong electron phonon interactions related to the layered crystal structures and the presence of high charge ionic species in proximity to metallic layers. Then ferromagnetic spin fluctuations are pair breaking and the main difference between the P and As compounds is the heavier mass of As, yielding a trend opposite to the usual isotope effect. Conversely, if the superconductivity of the Ni compound has a different origin (note the low $T_c$ of LaNiPO) a common spin-fluctuation based mechanism for the two Fe compounds is likely. Based on the suppression in the ferromagnetic susceptibility on doping the relevant fluctuations would be antiferromagnetic in nature. In both scenarios, doping plays a key role in the Fe based compounds. Electron doping reduces $N(E_F)$, which would lower pairing strength by reducing the phase space, and at the same time strongly suppresses ferromagnetic fluctuations, which are strongly pair breaking for singlet superconductivity. Furthermore, antiferromagnetic spin fluctuations are also weakened by electron doping, which is of relevance if these are involved in the pairing. One way of distinguishing these pictures would be via doping on the Fe site, e.g. with Co or Ni. Since the electronic structure near $E_F$ is from Fe $d$ bands, such doping would be much more strongly scattering than doping in the O layer and would be very detrimental to non-s wave spin fluctuation mediated superconductivity but not to s-wave superconductivity. It will be interesting to map out the similarities and differences between LaFeAsO and other superconductors with ionic metal type electronic structures, and systematically explore the relationship between spin-fluctuations and superconductivity.

16. The virtual crystal approximation differs from the rigid band approximation as it self-consistently includes the average change in potential, but neglects randomness. It is generally valid when the scattering effect of disorder is weak, as may be expected here because O does not participate in the states near the Fermi energy, and the O ions are located far from the Fe planes.

20. The antiferromagnetism discussed here is a nearest neighbor antiferromagnetism related to superexchange. Reports following the submission of this paper indicate that at zero doping there is a spin density wave instability, likely at the M point, which provides an actual antiferromagnetic ground state; J. Dong et al., arXiv:0803.3426 (2008); C. de la Cruz, et al., arXiv:0804.0795 (2008); M.A. McGuire, et al., arXiv:0804.0790 (2008).
