Abstract

Background: Acoustic positioning telemetry allows to collect large amounts of data on the movement of aquatic animals by use of autonomous receiver stations. Essential in this process is the conversion from raw signal detections to reliable positions. A new advancement in the domain is YAPS (Yet Another Positioning Solver), which combines the detection data on the hydrophones with a model of animal movement. This transparent, flexible and on-line available positioning algorithm overcomes problems related to traditional point-by-point positioning and filtering techniques. However, its performance has only been tested on data from one telemetry system, providing transmitters with stable burst interval. To investigate the performance of YAPS on different system parameters and settings, we conducted a simulation study.

Results: This paper discusses the effect of varying burst types, burst intervals, number of observations, reflectivity levels of the environment, levels of out-of-array positioning and temporal hydrophone resolution on positioning accuracy. We found that a hydrophone resolution better than 1 ms is required for accurate fine-scale positioning. The positioning accuracy of YAPS increases with decreasing burst intervals, especially when the number of observations is low, when reflectivity is high or when information out-of-array is used. However, when the burst interval is stable, large burst intervals (in the order of 1 to 2 minutes) can be chosen without strongly hampering the accuracy (although this results in information loss). With random burst intervals, the accuracy can be much improved if the random sequence is known.

Conclusions: As it turns out, the key to accurate positioning is the burst type. If a stable burst interval is not possible, the availability of the random sequence improves the positioning of random burst interval data significantly.

Keywords: YAPS; acoustic positioning telemetry; simulation study; sensitivity analysis; fine-scale positioning

1 Background

The study of aquatic animal behaviour has advanced largely with the development of radio and acoustic telemetry in the late 1950s [1, 2]. These underwater positioning techniques allow collecting large amounts of data on the movement of individual animals [2]. Since radio waves do not propagate in saltwater and the
technology is not yet suitable for fine-scale 2D positioning [3, 4], the most popular technique is acoustic telemetry [5]. This allows tracking of, for instance, diadromous fish species, which spent one part of their life in freshwater, and the other part in the sea. Acoustic positioning telemetry systems consist of stand-alone receivers or hydrophones fixed below the water surface. The animals of interest are tagged with acoustic transmitters, producing a signal every few seconds. The unique ID of the animal is encoded in the signal, which can be decoded by the hydrophones. The independence of the system enables researchers to collect huge datasets with minor data collection effort, once the set-up of the system is established. However, the main task starts once the data collection is done: converting the raw detections into reliable animal positions.

Most manufacturers provide a (paid) service or software to aid their customers in this process. Usually, they calculate the positions by use of the Time Difference Of Arrival (TDOA) algorithm, a hyperbolic positioning technique. When the signal is detected by 2 hydrophones, the differences in arrival time form a hyperbola of possible positions [6]. Detection on a third hydrophone is needed to provide a second hyperbola, and its intersection with the first hyperbola determines the position. This is a point-by-point method: every position is calculated independently of all other transmissions. If one hydrophone picks up an erroneous signal, the shift in the resulting hyperbola might completely dislocate the intersection point with other hyperbolas, causing a positioning error of up to several hundreds of meters. Usually, the positions come with an error indication that the customer can use to filter the data. However, these filters cannot cope with unpredictable phenomena such as reflections (personal experience and communication with manufacturers).

A recent advancement in the domain of acoustic positioning is YAPS (Yet Another Positioning Solver; [7]). In contrast to the TDOA algorithm, YAPS directly uses the time of arrival (TOA) data on all hydrophones and estimates a track by fitting a model of animal movement on these data. In an iterative process, YAPS simultaneously estimates the time of transmission, speed of sound (if no measurements available) and X and Y coordinate of all positions. The algorithm was originally developed for data obtained using equipment from one specific manufacturer (Lotek...
Wireless Inc., Newmarket, Ontario, Canada), with stable burst intervals. It has since been extended to random burst interval data, which is used in transmitters from other manufacturers (e.g. Thelma Biotel, Trondheim, Norway and Vemco, Halifax, Canada). However, its performance on random burst interval data and other system characteristics has not been rigorously tested.

Depending on the manufacturer, study site and research questions, widely different settings and system parameters might influence positioning accuracy. The extent of this influence depends on the applied positioning algorithm. The hardware determines specific settings, such as burst type and burst interval of the transmitters and temporal resolution of the hydrophone. The study site and set-up determine more general characteristics of the dataset, such as the number of detections per animal, origin of detections with respect to the receiver array, and the number of detections originating from reflected signals. In this study, we investigated the sensitivity of YAPS to these 6 parameters, which are further elaborated in the following paragraphs.

Transmitters are characterised by burst type and burst interval. The burst type determines the distribution of transmissions in time and can be stable or random. A random burst interval prevents that two transmitters simultaneously present in the receiver array, would ping in-phase and continuously overlap [8]. In fact, the interval is not truly random, but follows a computer-generated random sequence (i.e. pseudo-random). When this sequence is known, YAPS can utilise this information to predict the time of next transmission.

The choice of burst interval is mostly a trade-off between battery life of the transmitter and desired temporal resolution of the tracks. An additional constraint to burst interval is the duration of a transmission, which depends on the type of signal encoding. A frequently used signal encoding is pulse position modulation (PPM), where the ID is encoded in the time interval between 8 to 10 transmitted pulses, similar to Morse code [9, 10]. Since a PPM transmission takes 3 to 5 seconds [11], simultaneous transmissions of different animals can cause signal collision, which results in incomplete or corrupted transmissions. Hence, the amount of fish that
will be present simultaneously in the study area limits the allowable burst interval.

In contrast, Binary Phase Shift Key (BPSK) technology allows transmitting the encoded ID and even sensor data in $< 10$ ms, using phase modulation to encode information [10]. This technology is used for instance in the Vemco High Residency (HR) coded tags [11]. Another technique that allows similarly fast transmission is Code Division Multiple Access (CDMA), for instance used by Lotek [12, 13]. Both HR and CDMA allow the simultaneous presence of hundreds of animals, without limiting the frequency of signal transmission and hence allowing very short burst intervals.

The temporal resolution of the hydrophone expresses the accuracy with which a transmission’s time of arrival is measured, and depends on the electronics of the hydrophone and the physics of the signal transmission. In the case of PPM, the signal is decoded by analogue receivers [10]. A signal is recorded once it has reached a certain amplitude at the receiver, so the exact moment of time of arrival cannot be measured very precisely. Hence, PPM has an accuracy of 1 to 2 ms (personal communication with Vemco). In contrast, digital technologies such as BPSK and CDMA allow to measure the time of arrival up to sub-millisecond precision. Although this parameter affects the positioning accuracy independently of the positioning algorithm (since it sets a physical limit to the possible accuracy), a simulation study allows to investigate its effect on positioning accuracy in combination with other factors.

The number of detections (observations) per animal depends on the study set-up and fish swimming speed. When a fish swims fast through the hydrophone array and has a large burst interval-transmitter, very few signals might be detected on the hydrophone set. Point-by-point positioning methods such as TDOA can calculate a position no matter the number of transmissions, as long as the signal is detected by at least 3 hydrophones. In contrast, the YAPS algorithm needs a minimum amount of data to fit the movement model to the TOA data.

When little information is available inside the hydrophone array, it can be interesting to gain some information about the animal outside the array. Although the
main zone of interest is generally inside the array, for instance covering part of a lake, pond or marine area, or a section of a river or canal, the behaviour just before arriving at a covered river section might be useful extra information. TDOA methods have difficulties in treating signals that originate from outside the hydrophone array contours [6, 12]. Even to the extent that sometimes noisy tracks inside the array turn out to originate from out-of-array signals (personal experience).

Finally, the environment of the study site determines the number of reflections present in the data. Acoustic signals bounce off hard surfaces, causing an extension of the acoustic path: the reflected signal arrives later at the hydrophone than a direct signal, corrupting the TOA information and hence the resulting position. Many environments contain reflective surfaces: signals can for instance bounce off the ocean floor, the water surface and rock formations [14]. Concrete structures such as canal walls, sluices, dams and other human-made hydraulic structures, reflect even up to 98% of acoustic energy [15]. Mostly, hydrophones have at least some protection against reflected signals, for instance by use of blanking after detection of the direct signal [14]. However, the direct signal might not be heard, or if the site is large enough (i.e. the reflecting surface is far away), the reflected signal might arrive after the blanking period.

In this study, we investigated the sensitivity of the YAPS algorithm to the 6 parameters or system properties discussed above: burst type, burst interval, number of observations, reflectivity of the environment, out-of-array positioning and temporal hydrophone resolution. To this end, we simulated and estimated 50 tracks for all considered combinations of settings (17,850 tracks in total). We varied the parameters between values that we have encountered in our own experiences or in literature, or that are used by manufacturers we have worked with. This study aims to help users in the choice of system settings and to inform users and manufacturers on potential areas of improvement.
2 Results

In the following sections, we compare the performance of YAPS on the combined effect of signal characteristics (i.e. burst type and interval) and one of the following parameters: track length, reflectivity, out-of-array and temporal hydrophone resolution.

2.1 Effect of signal characteristics

Regardless of the value of other parameters, the performance of YAPS increases with burst type going from random over known-random to stable (Figure 1). In general, the error also increases with burst interval, but for large stable and known random burst intervals, burst interval does not affect the error significantly (except in highly reflective environments, Figure 1b). The standard deviation on the error increases with burst interval in all situations (Figure 2). Remarkably, stable and known random burst interval tracks have almost the same spread of errors, while the spread on random burst interval tracks can be 2 to 4 times higher.

2.2 Effect of number of observations

Tracks with large mean burst interval (especially 60 and 90 s) suffer most from short track lengths, with errors that are 2 to 4 times larger for tracks of 500 s than for tracks of 10,000 s (Figure 1a). However, the spread on the errors is large, extending from 0.2 to 72 m for tracks of 500 s with 60 to 90 s mean burst interval. Tracks longer than 2500 s only gain by increasing track length if the burst interval is random. Note that tracks of 500 s with 45, 60 or 90 s mean burst interval, contain only about 11, 8 or 6 observations respectively. For small burst intervals (up to 15 s, corresponding to at least 33 observations when the track length is 500 s), the error barely changes with track length, hence short tracks are no issue. For larger stable or known-random burst intervals (30 s and more), about 40 observations are needed (e.g. 60 s burst interval when track length is 2500 s) to minimise the error. Remarkably, for tracks of 10,000 s with random burst interval, some large errors still occur despite the smaller median error. Three tracks with only 6 observations could not be estimated by YAPS (at least not within 100 retries).
2.3 Effect of reflectivity

Multipath probabilities up to 5% have a minor effect on the performance of YAPS (Figure 1b). Higher probabilities cause an increase in errors, but only for large burst intervals: the errors are about twice as large for 10% versus 5% (or no) reflectivity, and this for all burst types. Small burst intervals up to 30 s are barely affected by increasing reflections. When the random sequence is known, the average of the median errors does not exceed 2.5 m in worst-case scenario (i.e. 10% reflections and largest burst interval), whereas a purely random burst interval then results in median errors of 10 m on average, and even up to 49 m.

2.4 Effect of out-of-array

For each burst type and all burst intervals, the error is about twice as large for tracks out-of-array versus tracks completely inside the array (Figure 1c). However, since the error on random burst interval tracks is already large (especially for large burst intervals), the effect of doubling the error is worse, resulting in median errors of 14 m on average. Despite larger errors, the form of the track is still captured quite well, even for random burst interval (Figure 3). When a track is half out-of-array, the error increases only slightly.

2.5 Effect of temporal hydrophone resolution

Improvement of the temporal hydrophone resolution affects the average error on all burst intervals when the burst type is stable or the random sequence is known (Figure 1d). However, for random burst intervals, resolutions better than 200 µs do not improve the track estimation further. While the error usually increases with increasing burst interval, for stable burst intervals this effect practically disappears with a resolution better than 200 µs.

3 Discussion

The parameter that mostly affects YAPS’ positioning accuracy is the burst type. When the next time of transmission is known (or at least follows a Gaussian distribution), the estimation of transmission time is quite simple and informed by
the surrounding transmission times. If this information is missing, the independent estimation of each time of transmission adds uncertainty and inaccuracies to the model. A stable burst interval hence results almost always in better accuracy, and quite large burst intervals (up to 60 s) can be chosen without really hampering the median accuracy on a track (although individual points might have higher errors). When using stable burst interval transmitters, care must be taken that transmitters are not pinging in phase, otherwise, their signals might collide constantly, making decoding impossible. To avoid this issue, known random burst intervals can be used. In this case, the availability of the random sequence significantly improves the results of YAPS estimations, actually approaching the accuracy reached with stable burst interval.

The choice of burst interval has a small influence on median error when the burst interval is stable or when the random burst interval sequence is known and when conditions are good (i.e. enough observations, a resolution better than 1 ms and reflectivity lower than 10%). In contrast, the error on random burst interval tracks increases rapidly with increasing burst interval. Even if the median error is not affected, the standard deviation per track does increase with burst interval in all situations, hence positions with larger error might be expected when the burst interval is large. Note that large burst intervals inherently come with information loss: between subsequent position, the best estimation of an animal’s behaviour is a straight line. On the other hand, very small burst intervals (around 1 s) require high temporal receiver resolution and result in excessively large datasets, challenging the processing limits of most personal computers and therefore hampering data handling and analysis.

In some cases, YAPS might fail to converge, which happened for 3 tracks of 6 observations in this simulation study. When a fish passes quickly through an array, and the burst interval of its transmitter is large, very few observations of its transmitter may be available. This provides very little information to fit the movement model and might result in a wide range of errors, from very small to very large. If the burst type is random, each time of transmission must be estimated separately, which additionally complicates the task with only about 10 TOA-data available.
For small burst intervals, about 30 observations are sufficient to avoid effects of too few data. For large burst intervals, it depends on the burst type: 40 observations are enough when the burst interval is stable or when the random burst interval sequence is known. For large random burst intervals, more observations are beneficial, but accuracy is never completely guaranteed: even at 10,000 s-track length, some tracks are estimated with high error. Hence, small burst intervals are advised when high accuracy is required.

Comparing different levels of reflection revealed that YAPS is very robust against errors due to reflections when the burst interval is small enough (i.e. not larger than 30 s), even up to 10% reflectivity. This robustness can be attributed to the use of the movement model, keeping positions within biologically plausible limits. When the burst interval is large and random, it is more difficult to intercept reflected signals, since the time of the next transmission is not known and has to be estimated independently. However, this effect is only significant for multipath probabilities larger than 5%. Moreover, if the random sequence is available, the average of median track errors stays limited to 2.5 m even for the largest burst interval. This shows the benefit and importance of knowing the random sequence.

The accuracy of YAPS is not much affected when only half of the track is outside of the array. However, tracks completely outside the array are only half as accurate, but still capture the (simulated) behaviour (Figure 3). This can be explained as follows: since YAPS uses Time Of Arrival directly, instead of Time Difference Of Arrival, it is geometrically based on intersecting circles instead of hyperbolas. The intersection of circles is less sensitive to errors in measured arrival time than the intersection of hyperbolas, but the uncertainty outside of the array is still larger than inside. The direct use of TOA (and hence circles) is only possible because YAPS iteratively estimates the time of transmission and uses all TOA information simultaneously. The latter also helps in avoiding completely erroneous positions once the transmitter is leaving the array contour. Although the main zone of interest is usually within the limits of the hydrophone array, sometimes it might be interesting to obtain information on how a fish is arriving at the study site. This
Regardless of the positioning algorithm, fine-scale positioning with high accuracy requires hydrophones with a sub-millisecond temporal resolution. The temporal hydrophone resolution depends on technological choices of the manufacturer and determines how accurate a positioning system can physically be. This simulation study allowed to quantify the combined effect of resolution and other parameters. For instance, a PPM system, that has a temporal resolution of 1 ms and typically an average burst interval not lower than 30 s, has a minimal error of about 2 m in best case scenario. In contrast, a CDMA system with 52 µs resolution, can be 20 cm accurate for the same burst interval.

### 4 Conclusions

The choice of burst type is of major importance to the performance of YAPS. Whereas the use of stable burst intervals leads in nearly all cases to better results, the poor performance on random burst interval data can be significantly improved when the random sequence is available. Therefore, we strongly urge manufacturers to store this information and make it available to customers.

In the design of a study, the choice of positioning system determines the temporal hydrophone resolution, which in turn determines the minimal accuracy that can be reached. Resolutions better than 1 ms are recommended for accurate fine-scale positioning. The choice of burst interval depends on many factors, such as the scale of the study, the research questions and hence the required accuracy. Whenever possible, small burst intervals are beneficial for the accuracy when low numbers of observations can be expected (i.e. fast-moving animals), in reflective environments and when there is interest in information from outside the hydrophone array. However, the benefit of small burst intervals is especially high for (unknown) random burst intervals. Very small burst intervals (around 1 s) result in excessively large datasets, needlessly complicating the data analysis.
5 Methods

5.1 Studied parameters

5.1.1 Signal characteristics: burst type and interval

In case of a stable burst interval (sbi), the YAPS algorithm can easily predict the time of the next transmission. In reality, the interval between transmission is not exactly constant, because the transmitter’s internal clock is imprecise and prone to drifting. Hence, the burst interval $t(i) - t(i - 1)$ can be approximated by a random walk or Gaussian distribution with standard deviation $\sigma$ [7]:

$$t(i) - t(i - 1) \sim N(t(i - 1) - t(i - 2), \sigma^2)$$ (1)

When the random sequence is unknown to the user, it can only be modelled as a random interval. In the YAPS algorithm, the random burst interval is approximated by a uniform distribution between minimum and maximum burst interval $(a, b)$, and is estimated for each ping independently, resulting in the following model for burst interval:

$$t(i) - t(i - 1) \sim U(a, b)$$ (2)

In contrast, if the random sequence $S$ is known, YAPS can utilise this information to predict the time of next transmission, while incorporating deviation caused by drift of the internal transmitter clock. The sequence of known random transmission times $t_{rbi}$ can be expressed as:

$$t_{rbi}(i) = t_{rbi}(i - 1) + S(i - 1)$$ (3)

and the burst interval can be modelled as:

$$t(i) - t(i - 1) | t_{rbi}(i - 1), t_{rbi}(i - 2) \sim N(t_{rbi}(i - 1) - t_{rbi}(i - 2), \sigma^2)$$ (4)

In this study, we varied the average burst interval between 1.2 and 120 s (Table 1).

5.1.2 Number of observations

Point-by-point positioning methods such as TDOA can calculate a position no matter the number of transmissions, as long as the signal is detected by at least 3
Table 1: Stable burst intervals (sbi) and corresponding minimum and maximum random burst intervals (rbi). Each stable burst interval is also the average of the corresponding random burst interval limits.

| sbi (s) | min rbi (s) | max rbi (s) |
|---------|-------------|-------------|
| 1.2     | 1.1         | 1.3         |
| 5       | 3           | 7           |
| 15      | 10          | 20          |
| 30      | 20          | 40          |
| 45      | 30          | 60          |
| 60      | 40          | 80          |
| 90      | 60          | 120         |

hydrophones. A fish with a large burst interval-transmitter, swimming fast through a hydrophone array, can result in one single TDOA position. In the YAPS algorithm, a minimum amount of data is required to fit the movement model to the TOA data. We verified the YAPS performance on tracks with a duration of 500, 1000, 2500, 5000 and 10,000 s. Note that the number of calculated positions depends on the burst interval, for instance, a track of 500 s with a 90-second mean burst interval, contains on average 6 positions.

5.1.3 Reflectivity of the environment

The reflectivity of the environment is expressed as the probability on a multipath signal p(MP). We introduced multipath by offsetting a fraction of the TOA-data with a random value between 0.035 and 0.209 s, which corresponds to an error of 50 to 300 m (assuming 1435 m/s sound speed in water). We varied p(MP) between 0 and 10% by 2.5% steps.

5.1.4 Out-of-array positioning

We verified the accuracy of YAPS in estimating out-of-array tracks by comparing tracks within the array, with the results of shifting tracks a half array-length out of the array (shift = 0.5), and completely out the of array (shift = 1).
Table 2: Temporal hydrophone resolutions for different systems and providers, which were used in the simulation study.

| System                | Temporal resolution |
|-----------------------|---------------------|
| Vemco PPM             | 1 ms                |
| Thelma Biotel PPM     | 1 ms                |
| Lotek 76 kHz          | 200 µs              |
| Vemco HR              | 130 µs              |
| Lotek 200 kHz         | 52 µs               |

5.1.5 Temporal hydrophone resolution

The temporal hydrophone resolution determines the accuracy that is physically achievable, for instance, 1 ms resolution corresponds to 1.4 m accuracy (assuming 1435 m/s sound speed in water). We compared YAPS performance on different temporal resolutions, corresponding to systems of the Vemco, Thelma Biotel and Lotek company (Table 2).

5.2 Set-up of the simulation study

To verify the influence of track length, we simulated 50 tracks for each 5 track lengths, in an array of 8 equally spread hydrophones (Figure 4). The simulated tracks were based on a correlated random walk movement model, with alternating periods of low and high movement. For each track, we also simulated sound speed data, following a random walk model. For each of the resulting 250 tracks (50*5), we simulated TOA data for the 7 burst intervals (Table 1) and 3 burst types. To verify the effect of other parameters, we used only the 50 tracks of track length 5000. On these tracks, we simulated TOA data for the 7 burst intervals and 3 burst types, combined with the 5 different probabilities of multipath p(MP) and 4 different temporal hydrophone resolutions, giving in total 189 settings (21*5 + 21*4).

We subjected the 50 tracks with length 5000 to 3 shifts relative to the array: no shift, half-out and completely out of array. For these 150 tracks, we again simulated TOA data for 7 burst intervals and 3 burst types (21 settings). Figure 5 summarises the simulation outline and the used R code can be found on-line [16].

All TOA data were calculated with 60% probability of missing detections, i.e. on average 3 (out of 8) hydrophones detecting the signal. The parameters p(MP) and
temporal hydrophone resolution were fixed at 2.5% and 200 µs respectively, when not varied. Finally, we ran the YAPS algorithm on each of the 17,850 TOA-datasets (250*21 + 50*189 + 150*21) to produce estimated tracks, allowing 100 attempts to converge.

7 Figures
Figure 1: YAPS performance in different settings. The 4 plots show the combined effect of burst interval properties with (a) varying track lengths, (b) probabilities of multipath p(MP), (c) shifts out-of-array and (d) temporal hydrophone resolution.

Each panel shows the results for random burst interval (blue), known random burst interval (purple) and stable burst interval (green) and for different mean burst intervals (x-axis). Each dot represents the median error of one track. Each combination of settings was run on 50 tracks. When not under variation, track length, p(MP), shift and resolution were respectively fixed at 5000, 2.5%, 0 and 200 µs. The line on top of the data is a LOESS (LOcally Estimated Scatterplot Smoothing) smoother with 95%-confidence interval showing respectively the general pattern (i.e. average value per setting) and the uncertainty on the smoother. To enhance the visualisation, median errors above 20 m are not shown. The maximum occurring median errors are 46 (a), 68 (b), 66 (c) and 21 m (d).
Figure 2: Same as in Figure 1, but each dot represents the standard deviation (sd) on the error of one track. The maximum occurring standard deviations are 62 (a), 62 (b), 79 (c) and 35 m (d).
Figure 3: Simulated track (green full line) and estimated yaps track (red dashed line) for the 3 shifts out-of-array (columns) and for mean burst intervals 1.2, 30 and 90 s (rows), with random burst interval (a) and known random burst interval (b). The black dots represent the hydrophones.
Figure 4: Example of a simulated track of 1000 s (green) and corresponding hydrophone array (black dots).

Figure 5: Graphic showing the simulation outline.
