Multiple exciton generation (MEG) is a process in which more than one exciton is generated upon the absorption of a high energy photon, typically higher than two times the band gap, in semiconductor nanocrystals. It can be observed experimentally using time resolved spectroscopy such as the transient absorption measurements. Quantification of the MEG yield is usually done by assuming that the bi-exciton signal is twice the signal from a single exciton. Herein we show that this assumption is not always justified and may lead to significant errors in the estimated MEG yields. We develop a methodology to determine proper scaling factors to the signals from the transient absorption experiments. Using the methodology we find modest MEG yields in lead chalcogenide nanocrystals including the nanorods.

Multiple exciton generation (MEG) via impact ionization, enhanced by discrete energy levels due to quantum confinement in semiconductor quantum dots (QDs), was proposed by Nozik in 2001. The process was experimentally observed by Klimov et al. in 2004 using pump-probe spectroscopy. Since then many researchers have investigated MEG in different QD materials using similar techniques, however, the yields have been found to be modest and the initial estimations of very high yields were attributed to the signal distortion due to the photo-charging of the quantum dots and the surface defects. Though these controversies have been rectified in recent experiments, the reported MEG yields still diverge significantly. Previous works have shown that the photoluminescence intensity of QDs is not proportional to the number of excitons in the system and proper scaling factors have to be used to quantify MEG yields in such experiments. As far as we know, all the MEG studies using pump-probe spectroscopy have so far assumed that the observed signal scales linearly with the number of excitons. The assumption can be related to the simple state-filling argumentation where the enhanced transmission of the probe beam, also known as the bleach signal, when the probe wavelength is tuned to energies above the band-gap, is due to the gradual filling of the low lying conduction band electron states that correspond to the band-edge transitions. This qualitative assumption does not consider any refinement due to the confinement-related correlation effects in QDs and might be insufficient for quantitative analyses. In this article we describe a modified analysis of the MEG yield based on transient absorption (pump-probe) measurements. We derive formulas to determine the calibration constants for the transient absorption measurements, and use them to calculate MEG yield in lead chalcogenide nanocrystals. Our calculations show that the photobleach signal due to a biexciton in nano-crystals is not always equal to twice the signal from a single exciton. Hence, proper scaling factors need to be determined for accurate calculation of the MEG yield. Though the methodology is general and applies to all the techniques that use time resolved spectroscopy with sub-picosecond time resolution, we focus on the time resolved bleach signal measured in our experiments.

The physical processes that lead to the relaxation of bi- or multi-excitions are different to that of the single excitons; Auger recombination dominates in the former while spontaneous emission plays the major role in the latter. The time scales of Auger recombination –few tens of picoseconds in case of samples investigated here – is distinctly different from that of the spontaneous emission –tens of nanoseconds. Consequently, the signatures of
the single and multi-excitons can be conveniently distinguished in a time-resolved spectroscopy measurement as demonstrated below.

Figure 1(a) shows the bleach signal of the probe pulse (probe photon energy, \( E_{\text{probe}} \sim 1.18 \text{ eV} \)) in PbS quantum dot (\( E_g \sim 1.07 \text{ eV} \)) under different pump intensities (excitation photon energy, \( E_x \sim 1.6 \text{ eV} \)). At low pump intensity, when the probability of sequential absorption of two photons and hence the population of multi-excitons is negligible, the bleach signal (red line) does not show appreciable decay after the action of the pump. While at high pump intensities, when more than one exciton are created per QD, the fast decay in the signal is due to the Auger recombination of the excitons when more than one exciton is created per QD. As the pump intensity is lowered (red curve, 1 \( \mu \text{J} \) energy per pulse), the probability that a QD absorbs more than one photon becomes negligible, consequently the fast decay vanishes. (b) Transient absorption signal when excited with high energy photons, \( E_{\text{ex}} \approx 3.76 \text{ eV} \), compared with the signal with low energy photon excitation.

The probe signal immediately after the pump excitation with photon energies less than the MEG threshold can be written as:

\[
S(t_0) = \sum_{i=1} a_i \rho(i)
\]

where \( S(t) \) denotes the time varying signal, \( t \) denotes the delay time with the subscript indicating the delay time between the pump and the probe pulse, \( a_i \) is the signal contribution due to the \( i \)-th exciton and \( P(i) \) denotes the probability of \( i \)-th exciton being populated by the absorption of \( i \) photons. As usual, we use Poisson distribution:

\[
P(i; \rho) = \frac{\exp(-\rho) \rho^i}{i!},
\]

where \( \rho \) is the average number of photons absorbed per quantum dot. The probe signal is given by \( S(t_0) = \rho \exp(-\rho)(a_1 + a_2 \rho / 2 + \cdots) \).

For small values of \( \rho (\rho < 0.25) \), the higher order terms can be neglected in our measurements. The probability of exciting tri- and higher excitons is less than 0.0022 when \( \rho < 0.25 \), which is insignificant compared to the probability of exciting single and bi-excitons. Moreover, the increase in the short time signal, \( S(t_0) \), shown in Figures 2 and 4 is slower than a linear rise. This clearly shows that the contribution to the signal from a higher \( n \)-th exciton (\( n>2 \)) is less than \( n \) times the signal from a single exciton. Note, that \( S(t_0) \) increases linearly with the intensity if the signal from the \( n \)-th exciton is \( n \) times the signal from a single exciton for all \( n \).

Neglecting the higher order terms, the signal can be written as:

\[
S(t_0) = a_1 \rho \exp(-\rho)(k \rho + \frac{2}{2}),
\]

where \( k = a_2 / a_1 \).

The probe signal at long time delay, when all the bi-excitons have decayed to the single excitons, is \( S(t) = a_1 \exp(-\rho) \Sigma_i = 1 \rho^i / i! \), which, when truncated after the second term, can be written as:
The relative strength of the biexciton contribution to the signal with respect to the single exciton contribution can be obtained from the ratio between the probe signal at the zero time delay and the long time delay:

\[
k = \frac{x(\rho + 2) - 2}{\rho},
\]

where \(x = S(t_0)/S(t_0)\). \(k\) is sufficient to quantify the MEG yield in the experiments where tri- or higher exciton formation by MEG can be neglected. Otherwise the higher order terms have to be included in Equ.(3) and Equ.(4) to determine even the calibration factors for the higher excitons (see the supporting information for the derivations of the equations in detail).

The average number of photons absorbed per quantum dot, \(\rho\), is related to the fluence: \(\rho = \sigma_{ab} I\), where \(\sigma_{ab}\) is the absorption cross-section at the pump wavelength. Using this relation in Equ.(5) has drawbacks because \(\sigma_{ab}\) is not always known, specially when new systems are investigated, and the fluence \(I\) can have large uncertainties unless one uses precisely calibrated detectors for specific wavelengths and accurately measures the focus spot size. To reduce the uncertainties we determine \(\rho\) by fitting the fluence dependent long time delay transient absorption signal \(S(t_0)\) to the following relation (see the supporting information for the derivation):

\[
S(I; t_0) = \alpha \left(1 - \exp\left(-\frac{I}{I_0 \rho_0}\right)\right),
\]

where \(\alpha\) is a constant, \(I_0\) is the reference fluence and \(\rho_0\) is the fitting parameter. This equation is particularly useful in experiments where the focus spot size of the pump beam is much bigger than the probe, like we are using here. When the probe focus is comparable to the pump, the bleach signal samples nano-particles that are excited with different intensities and the signals due to single and multi-excitions get averaged\(^9\). In this case a more generalized approach may be useful\(^a\).

Note that Equ.(6) uses the ratio of the fluences therefore any measurable quantity which is linearly related to the fluence can be used. In our experiments \(I\) represents the voltage response from a photo-detector. Using linear response from the photo-detector substantially reduces the uncertainties related to the determination of the fluence. In the following we use Equ.(5) and Equ.(6) to calculate the MEG yield in PbSe nanorods.

**Calculations.** The nanorods were prepared using the protocol described by Melinger et al\(^1\). Figure 2 shows the probe signal \((\lambda = 1100\ nm, E_{\text{probe}} \approx 1.13\ eV)\) at short time delay, \(t < 15\ ps\) (blue points), and at long time delay, \(t > 800\ ps\) (red points), after the excitation with the pump pulse \((\lambda = 775\ nm, E_{\text{exc}} \approx 1.6E_g)\) for the different pump intensities. The x-axis in the figure is the voltage response from a photo-diode monitoring the pump pulses, which is linearly proportional to the intensity of the pump. The red line is the fit to the long time delay signal using Equ.(6), which gives \(\rho_0(\rho_0 = 0.005\ V) = 0.024 \pm 0.002\); \(\rho\) for other intensities can be calculated using the relation \(\rho \propto I\).

We use the data point (boxed in Figure 2) with \(\rho = 0.226, S(t_0) = 2.51 \times 10^{-4} \pm 1 \times 10^{-4}\) and \(S(t_0) = 2.08 \times 10^{-4} \pm 3 \times 10^{-4}\) to determine \(k\), the relative contribution to the probe signal from biexcitons. For \(\rho = 0.226, P(2) = 0.02\) and \(P(3) = 0.0015\), so that tri- and higher exciton contribution can be safely neglected while at the same time there is enough contribution from the biexcitons. Using Equ.(5) we get \(k = 3.1 \pm 0.4\); error propagation from the uncertainties in \(x, \Delta x = 0.02\), and \(\Delta \rho = 0.002\), is used to compute the uncertainty in \(k\). For other values of \(\rho, 0.25 > \rho > 0.1\), we get \(3.5 > k > 3.1\), which is within the uncertainty range of \(k\) at \(\rho = 0.226\). For \(\rho < 0.1\) biexciton contribution is negligible while for \(\rho > 0.25\) tri-exciton contribution cannot be neglected. Similar calculations done on PbS QDs using the data shown in Figure 4 give \(k = 1.9 \pm 0.2\). So the scaling factors are not the same for different nano-particles. Previous works have indicated that they can depend on the probe wavelength as well\(^2\).

Figure 3 compares the probe signal when the PbSe nanorods are excited with \(3.2E_g\) (green curve; UV excitation) and \(1.6E_g\) (red curve; NIR excitation) photons. \(\rho = 0.139\) for the NIR excitation is calculated from the Figure 2 and the \(\rho = 0.094\) for UV excitation is calculated using the relation \(S(t_0) \propto \rho\) for \(\rho < 1\). For \(\rho < 0.1\) the probability of populating a bi-exciton is less than 0.005. We take this as the condition when the signal at long time delay is linearly proportional to \(\rho\) (see Equ.(4) and the supporting information for the details). The signals immediately and after long time delay following the UV excitation are \(5 \times 10^{10}\ photons\ cm^{-2}\ pulse^{-1}\). The average excitation fluence in this measurement is about \(5 \times 10^{10}\ photons\ cm^{-2}\ pulse^{-1}\). The average excitation fluence is calculated from the power of the pump beam measured by a powermeter calibrated for UV photons. For \(k = 3.1\) and \(\rho = 0.094\) the expected signal \(S_{\text{exp}}(t_0)\) calculated using Equ.(5) if there was no

---

**Figure 2** Transient absorption signal of PbSe nanorods at different excitation intensities: blue points shortly after the pump excitation and red points after a long time delay. Red line is the fit to the long time signal using Equ.(6). Upper axis is in the units of average excitation per QD.

**Figure 3** Time resolved probe signal for 1.6 eV (red curve) and 3.2 eV (green curve) pump-photon excitations. The average excitation fluence is \(5 \times 10^{10}\ photons\ cm^{-2}\ pulse^{-1}\). The band gap of the PbSe nanorods is about 1 eV. The green curve shows prominent fast initial decay even for lower average number of photons absorbed per quantum dot than for the red curve, which indicates MEG. The quantum yield of the MEG in this case is about 1.21.
MEG would be \((1.04 \pm 0.06) \times 10^{-4}\). The rest of the signal, \(S(t_0) - S_{\text{exc}}(t_0) = (0.44 \pm 0.08) \times 10^{-4}\), is due to the MEG. If \(\eta\) is the MEG yield, the fraction of the initially populated excitons that undergo MEG, then the total initial signal can be written as the sum of the signal from the bi-excitons, \(\eta k S_{\text{exc}}(t_0)\), and the single excitons, \((1 - \eta) S_{\text{exc}}(t_0)\):

\[
S(t_0) = \eta (k - 1) S_{\text{exc}}(t_0) + S_{\text{exc}}(t_0).
\]

Using the values for \(S(t_0)\), \(S_{\text{exc}}(t_0)\) and \(k\) in Eqn.(7), we get \(\eta = 0.21 \pm 0.05\). The corresponding quantum yield of the exciton generation is \(\phi = 1.21 \pm 0.05\).

Discussion

The MEG yield, \(\eta\), we have obtained in the NRs is slightly less than the yield in QDs but within the error range. Our results agree with some previous works, which show that Auger-like processes in NRs can be suppressed as compared to QDs. On the other hand, our results do not show significant enhancement in the MEG yield in NRs as observed recently. However, these conflicting results are not directly comparable as the previous calculations implicitly assume \(k = 2\), which leads to different yields even if the data are similar.

As far as we know all of the work on the quantification of the MEG yields based on the pump-probe measurements on QDs use \(k = 2\). This value is based on the assumption that the exciton bleach signal is due to state filling of the exciton bands. In the case of PbS QDs, the lowest band can accommodate 8 excitons. According to the assumption, the signal \(S(t_0)\) should scale linearly with intensity until the lowest exciton band is completely filled with the excitons. However, even for modest intensities for which \(\rho < 1\) the signal \(S(t_0)\) shown in Figure 2 for the NRs and Figure 4 for the PbS QDs deviates from the linear relationship. This indicates the possibility of exciton-exciton correlation effects in nano-particles in strong confinement regime. Though these effects have not been the focus of current research, further studies of such effects might be important for the deeper understanding of MEG in nano-particles.

Recent studies argue that the observed MEG yields in QDs may not improve the efficiency of photo-voltaic cells as compared to conventional solid state devices. Consequently, the current research trend has diverged into investigating nano-particles whose shape, size and composition are different from the idealized quantum dots.

It has been observed that these modifications can dramatically alter the spectroscopic properties of the nano-particles. In this context assuming \(k = 2\) when quantifying the MEG yields cannot be justified. Moreover, the MEG yields determined by photoluminescence measurements that take into account the proper scaling factors differ from the yields obtained by the pump-probe techniques. Use of the proper scaling factors in the pump-probe measurements could provide valuable insight into the discrepancies.

To conclude, our experiments show only modest MEG yields in PbSe NRs. Using our methodology we found that the bleach signal due to a biexciton in nano-particles is not always twice the bleach signal from a single exciton. It is important to explicitly compute the proper scaling factors that relate the populations to the signal amplitudes for the accurate quantification of the MEG yields in different nano-particles. It is also important to follow such a methodology for meaningful comparison the MEG yields obtained by using different experimental techniques.

Methods

Pump-probe spectroscopy. The schematic of the pump-probe setup is shown in Figure 1 of the Supplementary Information. The pulses (1.2 mJ pulse energy, 1 kHz repetition rate, center wavelength at 775 nm and pulse duration about 150 fs) are split from the amplified laser (CPA 2001) and are chopped at 500 Hz using a mechanical chopper. A Berek compensator is used to rotate the polarization of the pump beam and an analyzer is used to define the horizontal polarization. The intensity of the pump beam is controlled by the compensator/analyzer combination. The probe beam is polarized at the ‘magic angle’ with respect to the pump. The pump beam is focused into the sample using a lens with focal length 1 m. A little fraction of the pump beam is directed to the photo-detector to monitor the intensity of the pump pulses. The pump diameter at the focus is about 0.7 mm and the probe diameter is about 0.4 mm. The optical density of the samples at the excitation wavelengths is kept below 0.3. As the absorption cross-sections at the different excitation wavelengths are different, the signals need to be normalized by the concentration of the nano-crystals in the solution for the comparison. We have chosen to normalize them by the optical density at 450 nm. The samples are shaken during measurements to avoid degradation due to photocharging. Time error in the measurements is in the order of \(10^{-3}\) s. At such low error condition the signatures of photocharges can be seen as the pre-pump signal. We see such pre-pump signal in the cases with high pump fluence where the signal is in the order of \(10^{-2}\) s. All the measurements are done with pump fluence where the signal is at least an order of magnitude smaller (\(10^{-3}\) OD). The signal level in our measurements for MEG is in the order of \(10^{-2}\) OD, about three order of magnitude smaller than in the case when photocharging is discernible. No photocharging has been reported for the corresponding average number of excitons excited in the QDs. We probe above the band edge to avoid the artifacts due to ultrafast (sub-picosecond) de-polarization of the band edge by surface trapping. We also set \(S(t_0)\) to 3 ps after the pump pulse to avoid the sub-picosecond de-polarization component in the dynamics.

Materials and synthesis. Lead oxide (> 99.9%), oleic acid (OA, > 99.9%), selenium (99.5%, 100 mesh), triocetylphosphine (TOP, > 99%), tris(diethylamino)phosphine (TDP, 97%) and bio(trimethylsilyl) sulfide (TMS) were purchased from Aldrich. Solvents used in the synthesis included 1-octadecene (ODE, 90%), toluene (anhydrous, 99.8%), hexane (95%), heptane (96.7%), acetone (HPLC, > 99.8%), chloroform (> 99.9%) and ethanol (99.7%). All chemicals were used as received.

The synthesis method for the quantum dots can be found elsewhere. Briefly, 446 mg (2 mmol) lead PbO was dissolved in a mixture of 2 ml OA and 20 ml ODE then heated to 90°C under N₂. After PbO is completely decomposed to form colorless Pb oleate the solution further heated to various temperatures for QDs growth. 0.2 ml of TMS dissolved in 10 ml ODE was rapidly injected into the Pb oleate solution. The rapid injection of TMS solution into the reaction flask changed the color of the reaction mixture from colorless to deep brown. The reaction continued for 2 min. The solution in the flask was dissolved in 10 ml of toluene and was precipitated with methanol and acetone and then redispersed in non-polar solvent such as hexane and toluene for storage. To vary the size of the nano-particles, the injection temperature was changed. The TEM image of the QDs grown at 160°C are shown in Figure 3 of the Supplementary Information.
The synthesis method for the nanorods can be found elsewhere. Briefly, 4 mmol PbO and 10 mmol OA were mixed with ODE with a total weight of 16 g in a three-neck flask. The mixture was then purged with N₂ and heated to 150 °C to form colorless Pb oleate solution. Then 5.9 ml Se-TDP solution with 6 mmol Se was injected into Pb oleate solution containing 2 mmol PbO, 6 mmol OA and 31 mmol ODE at 130 °C and allowed to react for 2 mins. The aliquot was rapidly cooled using ice bath. Heptane and ethanol were used to purify the NRs for at least twice and finally dissolved in hexane. The morphology of the obtained nanorods is shown in Figure 4 of the Supplementary Information.

Data analysis. Here we summarize the main steps for the analysis of the MEG yield developed in this article based on the pump-probe spectroscopy. Measurements are done first using NIR pump for various pump intensities. The long time signal, S(t), is fitted with Equ.(6). The average number of excitons per quantum dot, \( \rho \), is obtained from the fitting. The calibration constant, \( k \), is calculated using Equ.(5) for \( \rho \approx 0.23 \). Once \( k \) is determined, a measurement is done using UV pump for very low pump intensity. For the measurement, the sample is diluted such that the optical density of the sample at 450 nm, \( \delta \), is determined, a measurement is done using UV pump for very low pump intensity. After the \( \rho \) for the UV pump is ascertained to be less than 0.1, the MEG yield is calculated as described in the section “Calculations”.
