(Dated: May 2, 2022)

The final black hole left behind after a binary black hole merger can attain a recoil velocity, or a “kick”, reaching values up to 5000 km/s. This phenomenon has important implications for gravitational wave astronomy, black hole formation scenarios, testing general relativity, and galaxy evolution. We consider the gravitational wave signal from the binary black hole merger GW200129, which has been shown to exhibit strong evidence of orbital precession. Using numerical relativity surrogate models, we constrain the kick velocity of GW200129 to \( v_f \sim 1542^{+747}_{-1098} \) km/s or \( v_f \gtrsim 698 \) km/s (one-sided limit), at 90% credibility. This marks the first identification of a large kick velocity for an individual gravitational wave event. Given the kick velocity of GW200129, we estimate that there is a less than 0.48% (7.7%) probability that the remnant black hole after the merger would be retained by globular (nuclear star) clusters. Finally, we show that kick effects are not expected to cause biases in ringdown tests of general relativity for this event, although this may change in the future with improved detectors.

Introduction.— When two black holes (BHs) orbit each other, they emit gravitational waves (GWs) which carry away energy and angular momentum. This causes the orbit to shrink in a runaway process that culminates in the merger of the BHs into a single remnant BH. At the same time, the GWs can also carry away linear momentum from the binary, shifting its center of mass in the opposite direction [1]. Most of the linear momentum is lost near the merger [2], resulting in a recoil or “kick” velocity imparted to the remnant BH.

Kicks are particularly striking for precessing binaries, in which the component BH spins are tilted with respect to the orbital angular momentum. For these systems, the spins interact with the orbital angular momentum as well as with each other, causing the orbital plane to precess [3]. Numerical relativity (NR) simulations revealed that the kick velocities for precessing binaries can reach values up to \( \sim 5000 \) km/s [4–6], large enough to be ejected from any host galaxy [7].

Kicks have important implications for BH astrophysics. Following a supermassive BH merger, the remnant BH can be displaced from the galactic center or ejected entirely [7], impacting the galaxy’s evolution [8], fraction of galaxies with central supermassive BHs [9], and event rates [10] for the future LISA mission [11]. For stellar-mass BHs like those observed by LIGO [12] and Virgo [13], kicks can limit the formation of heavy BHs. BH masses greater than \( \sim 65M_\odot \) are disfavored by supernova simulations [14, 15], but have been seen in GW events [16–18]. This could be explained by second-generation mergers [19], in which one of the component BHs is itself a remnant from a previous merger, and is thus more massive than the original stellar-mass progenitors. However, if the kick from the first merger is large enough, the remnant BH would get ejected from its host galaxy and would not participate in another merger.

Unfortunately, observational evidence of large kicks has been elusive. While various candidates from electromagnetic observations have been identified, their nature is debated [20]. Similarly, observing kicks using GW signals has been challenging [21–27]. For example, Varma et al. [21] used accurate models based on NR simulations to show that kicks from precessing binaries can be reliably inferred with LIGO-Virgo operating at their design sensitivity. However, the GW events analyzed in Ref. [21], which only included signals in the first two LIGO-Virgo observing runs [28], were not loud enough to constrain the kick.

Since then, the LIGO-Virgo detectors have been further upgraded, and the GW data from the third observing run were released in two stages, O3a [17] and O3b [18]. Notably, O3a provided the first evidence for precession in the ensemble population of merging binaries [29], even though none of the individual GW events unambiguously exhibited precession [17]. Finally, in O3b, the binary BH merger GW200129 was identified as the first individual GW event showing strong evidence of precession [18, 30]. Similarly, support for large kicks was identified in the ensemble population using the O3a data [31, 32], even though the individual events were not loud enough for an unambiguous kick inference [21, 33] (with the exception

* vijay.varma@aei.mpg.de; Marie Curie Fellow
of GW190814 [34], which was found to have a small kick of \( \sim 7^{+16}_{-7} \) km/s at 90% credibility [27].

In this Letter, we use the method developed in Ref. [21] to show that GW200129 has a large kick velocity \( \sim 1542^{+747}_{-1098} \) km/s at 90% credibility. As an application of the kick constraint, we compute the retention probability for the remnant BH of GW200129 in various host environments, and discuss the implications for the formation of heavy stellar-mass BHs. Finally, we show that Doppler effects due to the kick on the remnant mass measurement are small for this event, and should not impact ringdown tests of general relativity (GR).

**Methods.**— We follow the procedure outlined in Ref. [21] to infer the kick from a GW signal. We begin by measuring the binary source parameters following Bayes' theorem [35]:

\[
p(\lambda|d) \propto L(d|\lambda) \pi(\lambda),
\]

where \( p(\lambda|d) \) is the posterior probability distribution of the binary parameters \( \lambda \) given the observed data \( d \), \( L(d|\lambda) \) is the likelihood of the data given \( \lambda \), and \( \pi(\lambda) \) is the prior probability distribution for \( \lambda \). Under the assumption of Gaussian detector noise, the likelihood \( L(d|\lambda) \) can be evaluated for any \( \lambda \) using a gravitational waveform model and the observed data stream \( d \) [35]. A stochastic sampling algorithm is then used to draw posterior samples for \( \lambda \) from \( p(\lambda|d) \). We use the Parallel Bilby [36] parameter estimation package with the dynesty [37] sampler.

For quasicircular binary BHs, the full set of parameters \( \lambda \) is 15 dimensional [18]. This includes the 8D intrinsic parameters: the component masses \( (m_1 \text{ and } m_2) \) and spins \( (\chi_1 \text{ and } \chi_2) \), each of which is a 3D vector, as well as the 7D extrinsic parameters: the distance, right ascension, declination, time of arrival, coalescence phase, binary inclination, and polarization angle. Here, index 1 (2) corresponds to the heavier (lighter) BH, \( \chi_{1.2} \) are dimensionless spins with magnitudes \( \chi_{1.2} \leq 1 \), and masses refer to the detector frame redshifted masses. We also define the mass ratio \( q = m_1/m_2 \geq 1 \), total mass \( M = m_1 + m_2 \), and use geometric units with \( G = c = 1 \).

We employ the NR surrogate models NRSur7dq4 [38] and NRSur7dq4Remnant [38, 39] to infer the kick. Constructed by effectively interpolating between \( \sim 1500 \) precessing NR simulations, NRSur7dq4 predicts the gravitational waveform, while NRSur7dq4Remnant predicts the mass \( m_f \), spin \( \chi_f \), and kick velocity \( v_f \) of the remnant BH. We first obtain posterior samples for all 15 binary parameters using NRSur7dq4. The spins are measured in a source frame defined at a given reference point (see below): the \( z \)-axis lies along the instantaneous orbital angular momentum, the \( x \)-axis points along the line of separation from the lighter to the heavier BH, and the \( y \)-axis completes the right-handed triad. The remnant properties, which are also defined in the same source frame, depend only on the intrinsic parameters \( \Lambda = \{m_1, m_2, \chi_1, \chi_2\} \). Therefore, the posteriors for the remnant properties are obtained by evaluating NRSur7dq4Remnant on the \( \Lambda \) posterior samples; put simply, NRSur7dq4Remnant is a function of \( \Lambda \) that yields \( m_f, \chi_f \) and \( v_f \). We also compute the effective prior distribution for \( v_f \), by evaluating NRSur7dq4Remnant on \( \Lambda \) samples drawn from the prior \( \pi(\Lambda) \). The difference between the kick posterior and prior can be used to gauge how informative the data are about the kick [21].

Traditional modeling methods assume a phenomenological ansatz for the waveform [40, 41] or remnant properties [42–45], and calibrate remaining free parameters to NR simulations. NR surrogate methods [38, 39, 46, 47], on the other hand, take a data-driven approach and the models are trained directly against precessing NR simulations. In this approach, one first constructs a suitable numerical basis using a subset of the NR waveforms, and then builds fits across parameter space for the basis coefficients; we refer the reader to Ref. [38] for more details. NR surrogate models do not need to introduce additional assumptions about the underlying phenomenology which would necessarily introduce some systematic error. Through cross-validation studies, it has been shown that both NRSur7dq4 and NRSur7dq4Remnant achieve accuracies comparable to the simulations themselves [38], and as a result, are the most accurate models currently available for precessing systems, within their parameter space of validity: both models are trained on simulations with \( q \leq 4 \) and \( \chi_{1.2} \leq 0.8 \), but can be extrapolated to \( q \leq 6 \) and \( \chi_{1.2} \leq 1 \) [38]. As GW200129 shows significant support for large spins, we conduct some tests of the surrogate models in this regime in the Supplement [48].

For the prior in Eq. (1), we follow Ref. [18] and adopt a uniform prior for spin magnitudes (with \( 0 \leq \chi_1, \chi_2 \leq 0.99 \)) and redshifted component masses, an isotropic prior for spin orientations, sky location and binary orientation, and a distance prior (UniformSourceFrame [49]) that assumes uniform source distribution in comoving volume and time. In addition, we place the following constraints: \( q \leq 6 \) and \( 60 \leq M \leq 400 \). These constraints are motivated by the regime of validity of NRSur7dq4 [38], and are broad enough to safely encompass the posterior spread of GW200129 [18].

Because the spin directions are not constant for precessing binaries, spin measurements are inherently tied to a specific moment in the binary’s evolution. The standard approach is to measure the spins at the point where the frequency of the GW signal at the detector reaches a prespecified reference value, typically \( f_{\text{ref}} = 20 \) Hz [17]. This is mainly motivated by the fact that the sensitivity band of current detectors begins near this value [12, 13]. However, Ref. [50] recently showed that constraints on orbital-plane spin directions can be greatly improved by measuring the spins near the merger, in particular, at a fixed dimensionless reference time \( t_{\text{ref}}/M = -100 \) before the peak of the GW amplitude. This improvement can be attributed to the waveform being more sensitive to variations in the orbital-plane spin directions near the merger [50] \( (t_{\text{ref}}/M = -100 \text{ typically falls within } \sim 2 - 4 \text{ GW cycles before the peak amplitude, independent of the binary parameters [50].}) \).
For both reference points in Fig. 1, there is a clear preference for large orbital-plane spins for the heavier BH (large $\chi_1$ and $\cos \theta_1 \sim 0$). Even though the spin of the lighter BH is not well measured, this is sufficient for precession. We stress that while precessing binaries tend to have larger kicks [4-6], precession does not necessarily imply a large kick, and it is important to directly compute the kick velocity as we do in the next section. In particular, the kick can vary from zero to $\sim 5000$ km/s just by changing the azimuthal spin angles, even for systems with large orbital-plane spins [4-6].

Next, the azimuthal angles (especially $\phi_1$) in Fig. 1 are much better constrained at $t_{\text{ref}}/M = -100$, while the other parameters do not change significantly. This feature is key: even though the azimuthal angles are poorly constrained in the inspiral, they are well constrained at $t_{\text{ref}}/M = -100$ [50]. As the kick depends sensitively on the azimuthal angles near the merger [4], successfully measuring these angles at $t_{\text{ref}}/M = -100$ is critical for constraining the kick.

Spins measured at $f_{\text{ref}} = 20$ Hz can also be evolved consistently to $t_{\text{ref}}/M = -100$ using NRSur7dq4 dynamics [38]. In fact, this procedure is internally applied by NRSur7dq4Remnant if the spins are specified at $f_{\text{ref}} = 20$ Hz [38, 39]. Therefore, by construction, the kick posterior for individual GW events is independent of the reference point at which the spins are initially measured (modulo NRSur7dq4 spin evolution errors, which are small compared to the model errors [38, 47]). Therefore, for the purpose of this paper, the main benefit of the spin measurements at $t_{\text{ref}}/M = -100$ is to illustrate why a successful kick constraint is possible in the first place. The supplement of Ref. [31] discusses other benefits, in particular, for constraining the ensemble population of spins and kicks. In the rest of the paper, we will use the spin measurements at $t_{\text{ref}}/M = -100$.

As noted in Refs. [18, 30], the inference of precession in GW200129 depends on the waveform model used. In particular, while the phenomenological model IMRPhenomXPHM [40] recovers precession, the effective-one-body model SEOBNRv4PHM [41] does not. Among these models, only NRSur7dq4 is informed by precessing NR simulations and is more accurate by about an order of magnitude [38]. By contrast, SEOBNRv4PHM and IMRPhenomXPHM approximate precession effects by “twisting” the frame of an equivalent aligned-spin binary [40, 41]. Furthermore, Ref. [50] found that NRSur7dq4 is necessary to accurately measure the spin vectors $\chi_{1,2}$, in particular, the spin directions within the orbital plane [50], which have a strong influence on the kick [4]. Similarly, given the spin measurements, NRSur7dq4Remnant is necessary to accurately predict the kick velocity [21]. For these

We will adopt the $t_{\text{ref}}/M = -100$ reference point for the main results in this paper, but will show a comparison against $f_{\text{ref}} = 20$ Hz for completeness. As we will discuss below, the choice of reference point has a negligible impact on the kick inference itself, but comparing the spin posteriors at the two reference points helps illustrate why a kick constraint is possible in the first place. As a bonus, spin measurements at $t_{\text{ref}}/M = -100$ are convenient for inferring the kick as the NRSur7dq4Remnant model is also trained at this reference time [38]; this choice was found to lead to a more accurate remnant BH model in Refs. [38, 39].

GW200129 spin measurements. — GW200129 is the first GW event showing strong signs of precession [18, 30]. Figure 1 shows the posterior distribution for the mass ratio and spin parameters obtained using the NRSur7dq4 model at reference points $t_{\text{ref}}/M = -100$ and $f_{\text{ref}} = 20$ Hz; our constraints at $f_{\text{ref}} = 20$ Hz are consistent with those of Ref. [30]. The spin vectors $\chi_{1,2}$ are decomposed into magnitudes $\chi_{1,2}$, tilts angles $\theta_{1,2}$ with respect to the z-axis, and azimuthal angles $\phi_{1,2}$ with respect to the x-axis of the source frame. Due to precession, spins measurements vary between the two reference points but can be related by a spin evolution [38, 50].

Figures 1. Constraints on the mass ratio and spins for GW200129, at reference time $t_{\text{ref}}/M = -100$. The dark (light) regions represent the 50% (90%) credible bounds on joint 2D posteriors, while the diagonal plots show 1D marginalized posteriors. There is a preference for large $\chi_1$ and $\cos \theta_1 \sim 0$, meaning there is substantial spin in the orbital plane, which leads to precession. For comparison, we also show the 1D marginalized posteriors at $f_{\text{ref}} = 20$ Hz. The azimuthal spin angles (especially $\phi_1$) are much better constrained at $t_{\text{ref}}/M = -100$; this is critical for constraining the kick.
reasons, we treat NRSur7dq4 and NRSur7dq4Remnant as the preferred models for analyzing GW200129.

**GW200129 kick velocity.**— Figure 2 shows our constraints on the kick magnitude $v_f$ of GW200129, obtained by evaluating NRSur7dq4Remnant on the NRSur7dq4 A posteriors at $t_{ret}/M = -100$. In the left panel, we show the posterior and prior distributions for $v_f$, along with fiducial escape velocities for globular clusters [51], nuclear star clusters [51], giant elliptical galaxies [52], and Milky Way-like galaxies [52] for comparison. Unlike the events considered in Ref. [21], the $v_f$ posterior is clearly distinguishable from the prior, and there is substantial information gain about the kick.

The kick magnitude is constrained to $v_f \sim 1542_{-1098}^{+1747}$ km/s (median and 90% symmetric credible interval), or $v_f \gtrsim 698$ km/s (lower 10th percentile), making GW200129 the first GW event identified as having a large kick velocity. We note, however, that such large kick velocities are not surprising given previous constraints on the ensemble properties of merging binary BHs [31, 32]. For example, Fig. 3 of Ref. [31], which shows estimates of the ensemble kick distribution, includes nonnegligible support up to $v_f \sim 1500$ km/s.

The large kick of GW200129 raises the question of whether the remnant BH is ejected from its host environment. This has implications for the formation of heavy BHs through second-generation mergers in dense environments [19]. This formation channel is one possible way to explain observations of BHs with masses $\gtrsim 65M_\odot$ [16–18], which fall within the mass gap expected due to the (pulsational) pair-instability supernova processes [14, 15]. To address this, we compute the retention probability for the remnant BH of GW200129 in globular clusters and nuclear star clusters, both of which host dense stellar environments where merger remnants can potentially interact with other BHs and form binaries.

The right panel of Fig. 2 shows the cumulative distribution functions (CDFs) for the $v_f$ posterior and prior. As the posterior $CDF(v_f)$ denotes the probability that the kick magnitude of GW200129 is below $v_f$, we take it to be the probability that the remnant BH is retained by a host environment with an escape velocity of $v_f$. The vertical dotted lines indicate the maximum escape velocity $v_{\text{esc}}^{\text{max}}$ for various host environments; $CDF(v_{\text{esc}}^{\text{max}})$ sets the upper limit on the retention probability for that host. In particular, assuming $v_{\text{esc}}^{\text{max}} = 100$ km/s ($v_{\text{esc}}^{\text{max}} = 600$) for globular (nuclear star) clusters there is a less than 0.48% (7.7%) probability that the remnant BH of GW200129 is retained by those hosts. This is consistent with Refs. [31, 32], where globular clusters were already identified as an unlikely site for second generation mergers, even for more moderate kicks.

**Remnant mass and Doppler shifts.**— Our method provides predictions for both the magnitude and direction of the kick [21]. If the kick vector $v_f$ has a significant component along (or opposite) the line-of-sight, the observed GW signal can be influenced by the kick. At leading order,
The blue markers on the sphere show posterior samples for the pointing along the line-of-sight from the observer to the mass is given by (23):

\[ m_f = m_f + v_f \cdot \hat{n}/c, \]

where \( c \) is the speed of light and \( \hat{n} \) is the unit vector pointing along the line-of-sight from the observer to the source. The line-of-sight direction is obtained from our inference setup, parameterized by (\( t, \phi \)). \( t \) is the inclination angle between the orbital angular momentum and the line-of-sight to the observer, and \( \phi \) is the azimuthal angle to the observer in the orbital plane, both defined in the source frame at \( t_{\text{ref}}/M = -100 \).

Figure 3 shows the posterior distributions for the full kick vector \( v_f \) (also defined in the source frame at \( t_{\text{ref}}/M = -100 \)) and the line-of-sight direction. We find that the kick and the line-of-sight are not very well (anti-) aligned; therefore, we do not expect significant Doppler shifts for this signal. Finally, Fig. 4 shows the posterior distributions for \( m_f \) (obtained from \( \text{NRSur7dq4Remnant} \)) and \( m_f^{\text{DS}} \) (computed using Eq. (2)) for GW200129. As expected, the difference between these distributions is very small compared to the measurement uncertainty, meaning that tests of GR should not be impacted by the Doppler effect for this event. As detector sensitivity improves, this may not be the case, however, and it may be necessary to explicitly account for this effect [21].

Conclusions.— We use NR surrogate models for the gravitational waveform and the remnant BH properties to infer the kick velocity for the binary BH merger GW200129. The kick magnitude is constrained to \( v_f \sim 1542^{+747}_{-1088} \) km/s or \( v_f \gtrsim 698 \) km/s, at 90% credibility. Given the kick velocity, we estimate that there is at most a 0.48% (7.7%) probability that the remnant BH of GW200129 would be retained by globular (nuclear star) clusters. Finally, we show that the Doppler effect on the remnant mass is small compared to current measurement uncertainty; therefore ringdown tests of GR are not expected to be significantly impacted by the kick for this event.

Observational evidence for kicks has far reaching implications for BH astrophysics. GW200129 is the first
GW event identified as having a large kick velocity. Large kicks like this have been previously predicted based on the ensemble kick distribution of merging binary BHs [31, 32], and we can expect to see more such events as detector sensitivity improves. In particular, such observations can help resolve the mystery of the heavy BHs seen by LIGO-Virgo [16–18], by constraining the rate of second-generation mergers.

SUPPLEMENTAL MATERIALS

I. HIGH SPIN NR INJECTIONS

As GW200129 has a preference for a large $\chi_1$ (see Fig. 1), it is important to check the validity of the surrogate models NRSur7dq4 and NRSur7dq4Remnant in this regime. These models were trained on NR simulations with $\chi_{1,2} \leq 0.8$, but allow extrapolations to $\chi_{1,2} = 1$ [38]. Unfortunately, because NR simulations become expensive for large spins, very few simulations exist beyond $\chi_{1,2} = 0.8$ [57]. Therefore, the surrogate models have only been tested against a handful of NR simulations outside their training region [30, 38, 58]. While an exhaustive exploration is still prohibitively expensive, we conduct two additional tests using high spin NR simulations from Refs. [54, 59]. We inject these NR waveforms (in zero-noise) into a simulated LIGO-Virgo network operating at design sensitivity [60]. Then, we follow the same procedure as described in the main text, and use the NRSur7dq4 and NRSur7dq4Remnant models to recover the binary parameters and the kick.

We consider two NR waveforms, SXS:BBH:0178 [59] and SXS:BBH:2439 [54], which are publicly available through the SXS Catalog [61]. SXS:BBH:0178 corresponds to an equal mass binary with equal spins that are nearly extremal ($\chi_{1,2} \sim 0.99$), and aligned along the orbital angular momentum. Because of the symmetries (equal masses and spins), the kick for this binary is zero. SXS:BBH:2439 also corresponds to a binary with equal masses and large spins ($\chi_{1,2} \sim 0.95$), but with most of the spin in the orbital plane. In this case, while the spin magnitudes are equal, the directions are not. In fact, the spins were chosen to lie in the “superkick” configuration [54], with the in-plane spin components being anti-parallel to each other: this configuration leads to large kicks [4–6]. For both injections, we set $d_L = 400$ Mpc and $\theta_{JN} = \phi_{\text{ref}} = \pi/3$, where $d_L$ is the luminosity distance, $\theta_{JN}$ is the inclination angle between the total angular momentum $J$ and line of sight direction $\hat{N}$, and $\phi_{\text{ref}}$ is the reference orbital phase [18]. This leads to large signal-to-noise ratios (SNRs) of 72 and 63, respectively, for SXS:BBH:0178 and SXS:BBH:2439, and therefore provides a stringent test for the surrogate models. The rest of the binary parameters will be shown in figure insets below.

Fig. S1 shows the recovered mass ratio, spins, and kick for the two NR injections. In both cases, we find that the injected values are well recovered and lie within the 90% credible region of the posterior. We note, however, that the kick posterior for SXS:BBH:2439, while still capturing the true value, peaks below the injected value, which is related to the fact that the spin magnitudes also peak below the injected value. Similar trends were noted in Ref. [62], where it was found that the prior choice of uniform in spin magnitude and direction (which we also adopt in this work) may not be suitable for binaries with large spins. Therefore, an investigation on the impact of prior choices on the spin and kick inferences for high spin events may be necessary, especially as we approach the high SNRs considered in Fig. S1 with future detector improvements.

In summary, while these tests give us more confidence in the constraints placed on GW200129, we recommend a more exhaustive study to rule out any potential systematics in the surrogate models due to extrapolation to large spins, which we leave for future work.
Figure S1. Spin extrapolation tests for the NRSur7dq4 and NRSur7dq4Remnant models. Shown are the recovered kick magnitude, mass ratio and spin posteriors (measured at $t_{end}/M = -100$) for NR injections. The dark (light) regions represent the 50% (90%) credible bounds on joint 2D posteriors, while the diagonal plots show 1D marginalized posteriors. The injected binary parameters are shown as black lines, and are also given in the inset text. The left panel corresponds to an equal mass binary with nearly extremal ($\chi_{1,2} \sim 0.99$) but aligned spins. The right panel corresponds to an equal mass binary in a superkick configuration, with large spins ($\chi_{1,2} \sim 0.95$). In both cases, the injected values for the mass ratio, spins, and the kick are well recovered and lie within the 90% credible region of the posterior. As the in-plane spin is zero for the left panel, $\phi_1$ and $\phi_2$ are not meaningful parameters and the offset from the true value is not of concern.
