Abstract
We study the problem of designing a data structure that reports the positions of the distinct $\tau$-majorities within any range of an array $A[1, n]$, without storing $A$. A $\tau$-majority in a range $A[i, j]$, for $0 < \tau < 1$, is an element that occurs more than $\tau(j - i + 1)$ times in $A[i, j]$. We show that $\Omega(n \log(1/\tau))$ bits are necessary for any data structure able just to count the number of distinct $\tau$-majorities in any range. Then, we design a structure using $O(n \log(1/\tau))$ bits that returns one position of each $\tau$-majority of $A[i, j]$ in $O((1/\tau) \log \log_w (1/\tau) \log n)$ time, on a RAM machine with word size $w$ (it can output any further position where each $\tau$-majority occurs in $O(1)$ additional time). Finally, we show how to remove a $\log n$ factor from the time by adding $O(n \log \log n)$ bits of space to the structure.

1. Introduction
Given an array $A[1, n]$ of $n$ arbitrary elements, an array range query problem asks us to build a data structure over $A$, such that whenever a range $[i, j]$ with $1 \leq i \leq j \leq n$ arrives as an input, we can efficiently answer queries on the elements in $A[i, j]$ \cite{27}. Many array range queries arise naturally as subproblems of combinatorial problems, and are also of direct interest in data mining applications. Well-known examples are range minimum queries (RMQs, which seek the smallest element in $A[i, j]$) \cite{2}, top-$k$ queries (which report the $k$ largest elements in $A[i, j]$) \cite{3}, range selection queries (which report the $k$th largest element in $A[i, j]$) \cite{4}, and colored top-$k$ queries (which report the $k$ largest distinct elements in $A[i, j]$) \cite{17}.

An encoding for array range queries is a data structure that answers the queries without accessing $A$. This is useful when the values of $A$ are not of interest themselves, and thus $A$ may be deleted, potentially saving a lot of space. It is also useful when array $A$ does not fit in main memory, so it can be kept in secondary storage while a much smaller encoding can be maintained.

Preprint submitted to Algorithmica October 7, 2014
in main memory, speeding up queries. In this setting, instead of reporting an element in $A$, we only report a position in $A$ containing the element. Otherwise, in many cases we would be able to reconstruct $A$ via queries on the encodings, and thus these could not be small (e.g., $A[i]$ would be the only answer to the range query $A[i, i]$ for all the example queries given above). As examples of encodings, RMQs can be solved in constant time using just $2n + o(n)$ bits \cite{12} and, using $O(n \log k)$ bits, top-$k$ queries can be solved in $O(k)$ time \cite{15} and range selection queries in $O(\log k / \log \log n)$ time \cite{19}.

Frequency-based array range queries, in particular variants of heavy-hitter-like problems, are very popular in data mining. Queries such as finding the most frequent element in a range (known as the range mode query) are known to be harder than problems like RMQs. For range mode queries, known data structures with constant query time require nearly quadratic space \cite{22}. The best known linear-space solution requires $O(\sqrt{n / \log n})$ query time \cite{3}, and conditional lower bounds given in that paper show that a significant improvement is highly unlikely.

Still, efficient solutions exist for some useful variants of the range mode problem. An example are approximate range mode queries, where we are required to output an element whose number of occurrences in $A[i, j]$ is at least $1/(1 + \epsilon)$ times the number of occurrences of the mode in $A[i, j]$ \cite{14, 3}.

In this paper we focus on a popular variant of range mode queries called range $\tau$-majority queries, which ask to report any element that occurs more than $\tau(j - i + 1)$ times in $A[i, j]$. A version of the problem useful for encodings can be stated as follows (other variants are possible).

**Definition 1.** Given an array $A[1..n]$, a range $\tau$-majority query receives a range $[i, j]$ and returns one position in the range where each $\tau$-majority in $A[i, j]$ occurs. A $\tau$-majority is any element that occurs more than $\tau(j - i + 1)$ times in $A[i, j]$. When $\tau = 1/2$ we simply call it a majority.

Range majority queries can be answered in constant time by maintaining a linear space (i.e., $O(n)$-word or $O(n \log n)$-bit) data structure \cite{3}. Similarly, range $\tau$-majority queries can be solved in time $O(1/\tau)$ and linear space if $\tau$ is fixed at construction time, or $O(n \log \log n)$ space (i.e., $O(n \log n \log \log n)$ bits) if $\tau$ is given at query time \cite{1}.

In this paper, we focus for the first time on encodings for range $\tau$-majority queries. In this scenario, a valid question is how much space is necessary for an encoding that correctly answers such queries (we recall that $A$ itself is not available at query time). We answer that question in Section 3 proving a lower bound for any encoding that solves even a weaker query.

**Theorem 1.** Given a real number $0 < \tau < 1$, any encoding able to count the number of range $\tau$-majorities in any range $A[i, j]$ must use $\Omega(n \log(1/\tau))$ bits.

Since when using $O(n \log n)$ bits we have sufficient space to store $A[1..n]$\footnote{Or an equivalent array where each element is replaced by an identifier in $[1, n]$.}
Table 1: Space-time tradeoffs achieved. We mark the optimal spaces and times with a *.

| Condition          | Space (bits)          | Query time               |
|--------------------|-----------------------|--------------------------|
| $1/\tau = \omega(\text{polylog } n)$ | $O(n \log(1/\tau))$  | $O((1/\tau) \log \log_w (1/\tau))$ |
| $1/\tau = \Theta(\text{polylog } n)$  | $O(n \log(1/\tau))$  | $O(1/\tau)$ *            |
| $1/\tau = o(\text{polylog } n)$      | $O(n \log(1/\tau))$  | $O((1/\tau) \log n)$     |
| $1/\tau = o(\text{polylog } n)$      | $O(n \log \log n)$   | $O(1/\tau)$ *            |

(and achieve the optimal $O(1/\tau)$ time [1], encodings for range $\tau$-majorities are asymptotically interesting only for $\log(1/\tau) = o(\log n)$.)

In Section 4 we show how range $\tau$-majority queries can be solved using $O((n/\tau) \log \log n)$ bits of space and $O((1/\tau) \log n)$ query time. In Section 5 we reduce the space to the optimal $O(n \log(1/\tau))$ bits and slightly increase the time. After spending this time, the structure can report any of the positions of any majority in optimal time (e.g., the leftmost position of each $\tau$-majority in a negligible $O(1/\tau)$ time). In Section 6 we show how to build our structure in $O(n \log n)$ time. All the results hold on the RAM model with word size $w = \Omega(\log n)$ bits.

**Theorem 2.** Given a real number $0 < \tau < 1$, there exists an encoding using the optimal $O(n \log(1/\tau))$ bits that answers range $\tau'$-majority queries, for any $\tau \leq \tau' < 1$, in time $O((1/\tau) \log \log_w (1/\tau) \log n)$, where $w = \Omega(\log n)$ is the RAM word size in bits. It can report any occ further occurrence positions of the majorities in $O(\text{occ})$ time. The encoding can be built in $O(n \log n)$ time.

We note that the query time is simply $O((1/\tau) \log n)$ for polylogarithmic values of $1/\tau$. We also note that the time depends on $\tau$, not $\tau'$. In Section 6 we also show how to obtain a query time that is a function of $\tau'$, yet using $O(n \log^2(1/\tau))$ bits of space.

Finally, in Section 7 we derive a new variant that may use more space but slashes the $\log n$ term from the time complexity.

**Theorem 3.** Given a real number $0 < \tau < 1$, there exists an encoding using $O(n \log(1/\tau) + n \log \log n)$ bits that answers range $\tau'$-majority queries, for any $\tau \leq \tau' < 1$, in time $O((1/\tau) \log \log_w (1/\tau))$, where $w = \Omega(\log n)$ is the RAM word size in bits. It can report any occ further occurrence positions of the majorities in $O(\text{occ})$ time. The encoding can be built in $O(n \log n)$ time.

By combining the results of Theorems 2 and 3 we obtain the combinations given in Table 1.

2. Related Work

In this section we first cover the state of the art for answering range $\tau$-majority queries. Then, we survey a few results on bitmap representation, and
give a new result that will be useful for this paper. Again, all these results hold on the RAM model with word size \( w = \Omega(\log n) \) bits.

\[\text{1. Range Majories}\]

Range \( \tau \)-majority queries were introduced by Karpinski and Nekrich [16], who presented an \( O(n/\tau) \)-words structure with \( O((1/\tau)(\log \log n)^2) \) query time. Durocher et al. [3] improved their word-space and query time to \( O(n \log(1/\tau)) \) and \( O(1/\tau) \), respectively. Gagie et al. [13] presented another trade-off, where the space is \( O(n(H + 1)) \) bits and the query time is \( O((1/\tau) \log \log n) \). Here \( H \leq \lg n \) denotes the empirical entropy of the distribution of elements in \( A \) (we use \( \lg \) to denote the logarithm in base 2). The best current result in general is by Belazzougui et al. [1], where the space is \( O(n) \) words and the query time is \( O(1/\tau) \). All these results assume that \( \tau \) is fixed at construction time.

For the case where \( \tau \) is also a part of the query input, data structures of space (in words) \( O(n(H + 1)) \) and \( O(n \log n) \) were proposed by Gagie et al. [13] and Chan et al. [6], respectively. Very recently, Belazzougui et al. [1] brought down the space occupancy to \( O(n \log \log \sigma) \) words, where \( \sigma \) is the number of distinct elements in \( A \). The query time is \( O(1/\tau) \) in all cases. Belazzougui et al. [1] also presented a compressed solution using \( nH + o(n \log \sigma) \) bits, with slightly higher query time. All these solutions include a (sometimes compressed) representation of \( A \), thus they are not encodings. As far as we know, ours is the first encoding for this problem.

For further reading, we recommend the recent survey by Skala [27].

\[\text{2. Bitmap Representations}\]

Given a bitmap \( B[1,m] \) with \( n \) 1s, the operation \( \text{rank}(B,i) \) returns the number of 1s in \( B[1,i] \), whereas operation \( \text{select}(B,j) \) gives the position of the \( j \)-th 1 in \( B \). Both operations can be solved in constant time by storing \( o(m) \) bits in addition to \( B \) [18, 8]. When \( n \) is significantly smaller than \( m \), another useful representation [25] compresses \( B \) to \( n \lg \frac{m}{n} + O(n) + o(m) \) bits and retains constant time for both operations.

When \( n \) is much smaller than \( m \), even the \( o(m) \) extra bits of that compressed representation [25] are troublesome, and an Elias-Fano-based [11, 10] compressed representation [21] is useful. It requires \( n \lg \frac{m}{n} + O(n) \) bits, solves \( \text{select} \) in \( O(1) \) time and \( \text{rank} \) in \( O(\log \frac{m}{n}) \) time. The representation considers the positions of all the 1s in \( B \), \( x_i = \text{select}(B,i) \), and encodes the lowest \( b = \lceil \lg \frac{m}{n} \rceil \) bits of each \( x_i \) in an array \( L[1,n] \), \( L[i] = x_i \mod 2^b \). Then it defines a bitmap \( H[1,2n] \) that encodes the highest bits of the \( x_i \) values: all the bits at positions \( i + (x_i \div 2^b) \) are set in \( H \). Bitmap \( H \) is indexed for constant-time \( \text{rank} \) and \( \text{select} \) queries [18, 8]. The space for \( L[1,n] \) is \( n \lceil \lg \frac{m}{n} \rceil \) and \( H \) uses \( 2n + o(n) \) bits.

Now, \( \text{select}(B,j) = 2^b(\text{select}(H,j) - j) + L[i] \) can be computed in constant time. For \( \text{rank}(B,i) \), we observe that the \( h \)-th 0 in \( H \) represents the point where the position \( B[2^bh] \) is reached in the process of setting the 1s at positions \( i + (x_i \div 2^b) \), that is, \( x_{i-1} < 2^b h \leq x_i \). The number of 1s in \( H \) up to that position is \( \text{rank}(B,2^bh) \). Therefore, if we write \( i = 2^bh + l \), then \( \text{rank}(B,i) \) is
between \( j_1 = \text{rank}(H, \text{select}_0(H, h)) + 1 \) and \( j_2 = \text{rank}(H, \text{select}_0(H, h + 1)) \), where \( \text{select}_0(H, h) \) gives the position of the \( h \)th 0 in \( H \) and is also computed in constant time and \( o(n) \) bits \([18, 8]\). Now we binary search for \( l \) in \( L[j_1, j_2] \), which is increasing in that range. The range is of length at most \( 2^b \), so the search takes \( O(b) = O(\log \frac{m}{n}) \) time. The final position \( j \) returned by the search is \( \text{rank}(B, i) \).

The time can be improved to \( O(\log \log_w m + \log s) \) on a RAM machine of \( w \) bits by sampling, for each increasing interval of \( L \) of length more than \( s \), one value out of \( s \). Predecessor data structures are built on the samples of each interval, taking at most \( O((n/s) \log \frac{m}{n}) \) bits. Then we first run a predecessor query on \( L[j_1, j_2] \), which takes time \( O(\log \log_w \frac{m}{n}) \) \([23]\), and finish with an \( O(\log s) \)-time binary search between the resulting samples.

**Lemma 1.** A bitmap \( B[1, m] \) with \( n \) is can be stored in \( n \log \frac{m}{n} + O((n/s) \log \frac{m}{n} + n) \) bits, so that select queries take \( O(1) \) time and rank queries take \( O(\log \log_w \frac{m}{n} + \log s) \), for any \( s \), on a RAM machine of \( w \) bits.

### 3. Lower Bounds

We derive a lower bound on the minimum size range \( \tau \)-majority encodings may have, even if we just ask them to count the number of distinct \( \tau \)-majorities present in any range. The idea is to show that we can encode a certain combinatorial object in the array \( A \), so that the object can be recovered via range \( \tau \)-majority queries. Therefore, in the worst case, the number of bits needed to solve such queries must be at least the logarithm of the number of distinct combinatorial objects that can be encoded.

Consider a sequence of \( m \) permutations on \([3k]\). There are \((3k)!^m\) such sequences, thus any encoding for them must use at least \( m \lg((3k)!) \) bits in the worst case. Now consider the following encoding. Array \( A \) will have length \( n = 36 \cdot k \cdot m \). To encode the \( i \)th permutation, \( \pi_i = (x_1, x_2 \ldots x_{3k}) \), we will write 9 chunks on \( A[36k(i-1)+1, 36ki] \):

\[
\begin{align*}
1, 2, 3, \ldots, k, & \quad -1, -2, -3, \ldots, -2k, \quad x_1, x_2, x_3, \ldots, x_k \\
\textit{k+1}, \textit{k+2}, \textit{k+3}, \ldots, \textit{2k}, & \quad -1, -2, -3, \ldots, -2k, \quad x_1, x_2, x_3, \ldots, x_k \\
2k+1, 2k+2, 2k+3, \ldots, 3k, & \quad -1, -2, -3, \ldots, -2k, \quad x_1, x_2, x_3, \ldots, x_k \\
\textit{k+1}, \textit{k+2}, \textit{k+3}, \ldots, \textit{2k}, & \quad -1, -2, -3, \ldots, -2k, \quad x_{k+1}, x_{k+2}, x_{k+3}, \ldots, x_{2k} \\
\textit{2k+1}, \textit{2k+2}, \textit{2k+3}, \ldots, \textit{3k}, & \quad -1, -2, -3, \ldots, -2k, \quad x_{k+1}, x_{k+2}, x_{k+3}, \ldots, x_{2k} \\
1, 2, 3, \ldots, k, & \quad -1, -2, -3, \ldots, -2k, \quad x_{2k+1}, x_{2k+2}, x_{2k+3}, \ldots, x_{3k} \\
\textit{k+1}, \textit{k+2}, \textit{k+3}, \ldots, \textit{2k}, & \quad -1, -2, -3, \ldots, -2k, \quad x_{2k+1}, x_{2k+2}, x_{2k+3}, \ldots, x_{3k} \\
2k+1, 2k+2, 2k+3, \ldots, 3k, & \quad -1, -2, -3, \ldots, -2k, \quad x_{2k+1}, x_{2k+2}, x_{2k+3}, \ldots, x_{3k} \\
\end{align*}
\]
We will set \( \tau = 1/(2k+2) \) and perform \( \tau \)-majority queries on parts of \( A \) to recover any permutation.

Let us start obtaining \( \pi_i(1) = x_1 \). Let \( C[1, 36] = A[36k(i - 1) + 1, 36k] \). Consider an interval of the form

\[
C[\ell, 3k + g] = \ell, \ell + 1, \ldots, k, -1, -2, \ldots, -2k, x_1, x_2, \ldots, x_g,
\]

for \( 1 \leq \ell, g \leq k \). Note that \( x_1, \ldots, x_g \) are the only values that may appear twice in \( C[\ell, 3k + g] \); precisely, if they belong to \( \{\ell, \ldots, k\} \). Note that elements appearing once in \( C[\ell, 3k + g] \) are not \( \tau \)-majorities, since \( 1 \leq \tau(3k + g - \ell + 1) \) for any values \( k, \ell, g \). On the other hand, if an element appears twice in \( C[\ell, 3k + g] \), then it is a \( \tau \)-majority, since \( 2 > \tau(3k + g - \ell + 1) \) for any values \( k, \ell, g \).

With this tool, we can discover \( x_1 \) as follows. First, we ask whether there is a \( \tau \)-majority in \( C[1, 3k + 1] \). If there is none, then \( x_1 \notin \{1, \ldots, k\} \), and we have to look for it elsewhere (in \( C[4k + 1, 8k] \) or \( C[8k + 1, 12k] \)). Assume there is a \( \tau \)-majority in \( C[1, 3k + 1] \); then \( x_1 \in \{1, \ldots, k\} \). Now we query the range \( C[2, 3k + 1] \). If there is no \( \tau \)-majority, then \( x \notin \{2, \ldots, k\} \), and we conclude that \( x_1 = 1 \). If there is, then \( x \in \{2, \ldots, k\} \) and we query the range \( C[3, 3k + 1] \). If there is no \( \tau \)-majority, then \( x \notin \{3, \ldots, k\} \) and we conclude that \( x_1 = 2 \), and so on. The process is continued, if necessary, until querying the range \( C[k, 3k + 1] \). If, instead, we had originally found out that \( x \notin \{1, \ldots, k\} \), then we look for it analogously in \( C[4k + 1, 8k] \) or \( C[8k + 1, 12k] \).

To look for \( x_2 \), we consider similarly ranges of the form \( C[\ell, 3k + 2] \), with identical reasoning. This time, it is possible that element \( x_1 \) is also counted as an answer, but since we already know the value of \( x_1 \), we simply subtract 1 from the count in any range \( C[\ell, 3k + 2] \) with \( \ell \leq x_1 \). This process continues analogously until we identify \( x_k \). The other two thirds of \( \pi_i \) are extracted analogously from \( C[12k + 1, 24k] \) and \( C[24k + 1, 36k] \).

Example. Consider encoding \( m = 1 \) permutation \( \pi = (1 \ 5 \ 3 \ 9 \ 2 \ 4 \ 6 \ 8 \ 7) \), of size \( 3k = 9 \). Then we set \( \tau = 1/8 \) and the array \( A[1, 108] \) is as follows:

\[
\begin{align*}
1, 2, 3, &\quad -1, -2, -3, -4, -5, -6, \quad 1, 5, 3 \\
4, 5, 6, &\quad -1, -2, -3, -4, -5, -6, \quad 1, 5, 3 \\
7, 8, 9, &\quad -1, -2, -3, -4, -5, -6, \quad 1, 5, 3 \\
1, 2, 3, &\quad -1, -2, -3, -4, -5, -6, \quad 9, 2, 4 \\
4, 5, 6, &\quad -1, -2, -3, -4, -5, -6, \quad 9, 2, 4 \\
7, 8, 9, &\quad -1, -2, -3, -4, -5, -6, \quad 9, 2, 4 \\
1, 2, 3, &\quad -1, -2, -3, -4, -5, -6, \quad 6, 8, 7 \\
4, 5, 6, &\quad -1, -2, -3, -4, -5, -6, \quad 6, 8, 7 \\
7, 8, 9, &\quad -1, -2, -3, -4, -5, -6, \quad 6, 8, 7
\end{align*}
\]

Now we will find \( x_1 \) (which is 1, but we do not know it yet). Since \( A[1, 10] \) has a \( \tau \)-majority, we know that \( x_1 \in \{1, 2, 3\} \). Since \( A[2, 10] \) has no \( \tau \)-majority, we know that \( x_2 \notin \{2, 3\} \), thus we learn \( x_1 = 1 \).
Now let us find $x_2$. Since $A[1, 11]$ has one $\tau$-majority, which we know corresponds to $x_1 = 1$, we conclude that $x_2 \notin \{1, 2, 3\}$. Thus we will have to find it analogously in $A[13, 24]$ or in $A[25, 36]$.

Now let us find $x_3$. Since $A[1, 12]$ has two $\tau$-majorities, one of which we know corresponds to $x_1 = 1$, and the other we know does not correspond to $x_2$, we conclude that $x_3 \in \{1, 2, 3\}$. Now $A[2, 12]$ has one $\tau$-majority. We know it does not correspond to $x_1 = 1$ (as it falls outside the range) nor to $x_2$ (as it is not in this subset). Then it follows that $x_3 \in \{2, 3\}$. Finally, since $A[3, 12]$ still has one $\tau$-majority, we conclude $x_3 \in \{3\}$, thus $x_3 = 3$.

Element $x_2$ will be found in $A[13, 24]$. Elements $x_4, x_5, x_6$ will be obtained from $A[37, 72]$ and elements $x_7, x_8, x_9$ from $A[73, 108]$. $\square$

Now, since $n = 36km$ and $\tau = 1/(2k + 2)$, we have that any encoding able to answer the above queries requires at least

$$m \log ((3k)!) > m (3k \log(3k) - 3k \log e + 1) > \frac{n}{12} \left(\log \left(\frac{3}{2\tau} - 3\right) - \log e\right)$$

bit. This is $\Omega(n \log(1/\tau))$ unless $1/\tau \leq 2 + \frac{2}{3}e = O(1)$, thus it is sufficient that we show that $\Omega(n)$ is a lower bound for any constant $\tau \geq 1/(2 + \frac{2}{3}e) > 1/4$.

To show that $\Omega(n)$ bits are necessary for any $\tau \geq 1/4$, consider encoding a bitmap $B[1, m]$ in an array $A[1, 4m]$ so that, if $B[i] = 0$, then $A[4(i-1)+1] = 1$, $A[4(i-1)+2] = 2$, $A[4(i-1)+3] = 3$, and $A[4i] = 4$. Instead, if $B[i] = 1$, then $A[4(i-1)+1, 4i]$ if $B[i] = 1$. As there are $2^m$ possible bitmaps $B$ and our array is of length $n = 4m$, we need at least $m = n/4 = \Omega(n)$ bits for any encoding. Then the proof of Theorem 4 is complete.

4. An $O((n/\tau) \log \log n)$ Bits Encoding for Range $\tau$-Majorities

In this section we obtain an encoding using $O((n/\tau) \log \log n)$ bits and solving $\tau$-majority queries in $O((1/\tau) \log n)$ time. In the next section we improve the space usage. We assume that $\tau$ is fixed at construction time. At query time, we will be able to solve any $\tau'$-majority query for any $\tau \leq \tau' < 1$.

4.1. The Basic Idea

Consider each distinct symbol $x$ appearing in $A[1, n]$. Now consider the set of all the segments $S_x$ within $[1, n]$ where $x$ is a $\tau$-majority (this includes, in particular, all the segments $[k, k]$ where $A[k] = x$). Segments in $S_x$ may overlap each other. Now let $A_x[1, n]$ be a bitmap such that $A_x[k] = 1$ iff position $k$ belongs to some segment in $S_x$. We define a second bitmap related to $x$, $M_x$, so that if $A_x[k] = 1$, then $M_x[rank(A_x, k)] = 1$ iff $A[k] = x$, where operation rank was defined in Section 2.2.

---

4Bounding $\log(3k)!$ with integrals one obtains $3k \log(3k/e) + 1 \leq \log(3k)! \leq (3k + 1) \log((3k + 1)/e) + 1$. 
Example. Let our running example array be $A[1, 7] = \langle 1 3 2 3 3 1 1 \rangle$, and $\tau = 1/2$. Then we have the segments $S_x$:

$$S_1 = \{ [1, 1], [6, 6], [7, 7], [6, 7], [5, 7] \},$$

$$S_2 = \{ [3, 3] \},$$

$$S_3 = \{ [2, 2], [4, 4], [5, 5], [4, 5], [2, 4], [3, 5], [4, 6], [2, 5], [1, 5], [2, 6] \},$$

and the corresponding bitmaps $A_x$:

$$A_1 = \langle 1 0 0 1 1 1 \rangle, \quad A_2 = \langle 0 0 1 0 0 0 0 \rangle, \quad A_3 = \langle 1 1 1 1 1 1 0 \rangle.$$ 

Finally, the corresponding bitmaps $M_x$ are:

$$M_1 = \langle 1 0 1 1 \rangle, \quad M_2 = \langle 1 \rangle, \quad M_3 = \langle 0 1 0 1 1 0 \rangle.$$ 

Then, the following result is not difficult to prove.

Lemma 2. An element $x$ is a $\tau'$-majority in $A[i, j]$ iff $A_x[k] = 1$ for all $i \leq k \leq j$, and 1 is a $\tau'$-majority in $M_x[\text{rank}(A_x, i), \text{rank}(A_x, j)]$.

Proof. If $x$ is a $\tau'$-majority in $A[i, j]$, then it is also a $\tau$-majority. Thus, by definition, $[i, j] \in S_x$, and therefore all the positions $k \in [i, j]$ are set to 1 in $A_x$. Therefore, the whole segment $A_x[i, j]$ is mapped bijectively to $M_x[\text{rank}(A_x, i), \text{rank}(A_x, j)]$, which is of the same length. Finally, the number of occurrences of $x$ in $A[i, j]$ is the number of occurrences of 1 in $M_x[\text{rank}(A_x, i), \text{rank}(A_x, j)]$, which establishes the result.

Conversely, if $A_x[k] = 1$ for all $i \leq k \leq j$, then $A[i, j]$ is bijectively mapped to $M_x[\text{rank}(A_x, i), \text{rank}(A_x, j)]$, and the 1s in this range correspond one to one with occurrences of $x$ in $A[i, j]$. Therefore, if 1 is a $\tau'$-majority in $M_x[\text{rank}(A_x, i), \text{rank}(A_x, j)]$, then $x$ is a $\tau'$-majority in $A[i, j]$.

Example. Value 1 is a majority in $A[5, 7]$, and it holds that $A_1[5, 7] = \langle 1 1 1 \rangle$ and $M_1[\text{rank}(A_1, 5), \text{rank}(A_1, 7)] = M_1[2, 4] = \langle 0 1 1 \rangle$, where 1 is a majority.

Thus, with $A_x$ and $M_x$ we can determine whether $x$ is a majority in a range.

Lemma 3. It is sufficient to have rank-enabled bitmaps $A_x$ and $M_x$ to determine, in constant time, whether $x$ is a $\tau'$-majority in any $A[i, j]$.

Proof. We use Lemma 2. We compute $i' = \text{rank}(A_x, i)$ and $j' = \text{rank}(A_x, j)$. If $j' - i' \neq j - i$, then $A_x[k] = 0$ for some $i \leq k \leq j$ and thus $x$ is not a $\tau$-majority in $A[i, j]$, hence it is also not a $\tau'$-majority. Otherwise, we find out whether 1 is a $\tau'$-majority in $M_x[i', j']$, by checking whether $\text{rank}(M_x, j') - \text{rank}(M_x, i' - 1) > \tau'(j' - i' + 1)$.

To find any position $i \leq k \leq j$ where $A[k] = x$, we need the operation $\text{select}(B, j)$, defined in Section 2.2. Then, for example, if $x$ is a $\tau'$-majority in $A[i, j]$, its leftmost occurrence in $A[i, j]$ is $i - i' + \text{select}(M_x, \text{rank}(M_x, i' - 1) + 1)$. In general, for any $1 \leq t \leq \text{rank}(M_x, j') - \text{rank}(M_x, i' - 1)$, we can retrieve the $t$th occurrence with $i - i' + \text{select}(M_x, \text{rank}(M_x, i' - 1) + t)$.
4.2. Coalescing the Bitmaps

We cannot afford to store (and probe!) all the bitmaps $A_x$ and $M_x$ for all $x$, however. The next lemma is the first step to reduce the total space to slightly superlinear.

Lemma 4. For any position $A[k] = x$ there are at most $2\lceil 1/\tau \rceil$ 1s in $A_x$.

Proof. Consider a process where we start with $A[k] = \perp$ for all $k$, and set the values $A[k] = x$ progressively. We will distinguish three kinds of changes.

(1) New segments around $A[k]$ are created in $S_x$. Setting $A[k] = x$ creates in $S_x$ all the segments of the form $[k - k_l, k + k_r]$ for $1 > \tau(k_r + k_l + 1)$, or $k_l + k_r < 1/\tau - 1$. Their union is the area $A_x[k - \lceil 1/\tau \rceil + 2, \ldots, k + \lceil 1/\tau \rceil - 2] = 1$, which may increase the number of 1s in $A_x$ by up to $2\lceil 1/\tau \rceil - 3$.

(2) Segments already covering $A[k]$ are extended. Any maximal segment $[l, r] \in S_x$ covering $A_x[k]$ contains $c > \tau(r - l + 1)$ occurrences of $x$, but it holds that $c \leq \tau(r - l + 2)$, otherwise there would also exist segments $[l - 1, r]$ and $[l, r + 1]$ in $S_x$, and $[l, r]$ would not be maximal. Therefore, adding one more occurrence, $A[k] = 1$, we get $c + 1 \leq \tau(r - l + 2 + 1/\tau)$ occurrences in $[l, r]$. Now it holds that $x$ may be a $\tau$-majority in segments $[l - k_l, r + k_r]$ for all $0 \leq k_l + k_r < 1 + \tau$ (i.e., where $c + 1 > \tau(r - l + 1 + k_l + k_r)$, using only that $c + 1 \leq \tau(r - l + 2 + 1/\tau)$), and therefore we can extend $[l, r]$ to the left by up to $\lceil 1/\tau \rceil$, or to the right by up to $\lceil 1/\tau \rceil$.

(3) Segments reaching close to $A[k]$ are extended. The same reasoning as for the previous case applies, even if $[l, r]$ does not originally contain position $k$. There are more restrictions, since now $[l - k_l, r + k_r]$ must be so that it contains $k$, and the same limit $0 \leq k_l + k_r < 1 + 1/\tau$ applies. Thus, in addition to being possible to extend them by at most $\lceil 1/\tau \rceil$ cells in either direction, position $k$ must lie within the extended area.

Total extension. The three cases above are superimposed. Let $\ell_l$ and $\ell_r$ the closest positions $\ell_l \leq k \leq \ell_r$ where $A_x[\ell_l] = A_x[\ell_r] = 1$. Then, if $\ell_l = k$, we can set at most $\lceil 1/\tau \rceil$ new 1s in $A_x$ to the left of $k$ by extending segments using case (2). Otherwise, if $k - \ell_l \leq \lceil 1/\tau \rceil$, we can cover the area $A_x[\ell_l + 1, \ldots, k]$ and add up to $\lceil 1/\tau \rceil - (k - \ell_l)$ further cells to the left, using case (3). Otherwise, if $k - \ell_l > \lceil 1/\tau \rceil$, we set $\lceil 1/\tau \rceil - 2$ cells to the left, apart from $k$, using case (1). The same reasoning applies to the right, and therefore $2\lceil 1/\tau \rceil$ is an upper bound to the number of 1s in $A_x$ produced by each new occurrence of $x$ in $A$.

The lemma shows that all the $A_x$ bitmaps add up to $O(n/\tau)$ 1s, and thus the lengths of all the $M_x$ bitmaps add up to $O(n/\tau)$ as well (recall that $M_x$ has one position per 1 in $A_x$). Therefore, we can store all the $M_x$ bitmaps within $O(n/\tau)$ bits of space. We cannot, however, store all the $A_x$ bitmaps, as they may add up to $O(n^2)$ 0s (note there can be $O(n)$ distinct symbols $x$), and we still cannot probe all the $A_x$ bitmaps for all $x$ in $o(n)$ time.

9
Instead, we will coalesce all the bitmaps \( A_x \) into a smaller number of bitmaps \( A'_x \) (which will be called coalesced bitmaps). Coalescing works as follows. Let us write \( A[i, j] = b \) to mean \( A[\ell] = b \) for all \( i \leq \ell \leq j \). We start with all \( A'_x[1, n] = 0 \) for all \( r \). Then we take each maximal area of all 1s of each bitmap, \( A_x[i, j] = 1 \), choose some \( r \) such that \( A'_x[i - 1, j + 1] = 0 \), and set \( A'_x[i, j] = 1 \). That is, we copy the run of 1s from \( A_x \) to some coalesced bitmap \( A'_x \) such that the run does not overlap nor touch other previous runs already copied (i.e., there must be at least one 0 between any two copied runs of 1s). We associate to each such coalesced bitmap \( A'_x \) a bitmap \( M'_x \) where the areas of each \( M_x \) corresponding to each coalesced area of \( A_x \) are concatenated, in the same order of the coalesced areas. That is, if \( A'_x[i_t, j_t] = 1 \), the \( t \)th left-to-right run of 1s in \( A'_x \), was copied from \( A_x \), then \( M_x[\text{rank}(A_x, i_t), \text{rank}(A_x, j_t)] \) will be the \( t \)th segment appended to \( M'_x \).

**Example.** We can coalesce the whole bitmaps \( A_1 \) and \( A_2 \) into \( A' = (10101111) \), with the corresponding bitmap \( M' = (11011) \).

The coalesced bitmaps \( A'_x \) and \( M'_x \) will replace the original bitmaps \( A_x \) and \( M_x \). At query time, we check for the area \([i, j] \) of each coalesced bitmap using Lemma 3. We cannot confuse the areas of different symbols \( x \) because we force that there is at least one 0 between any two areas. We cannot report the same \( \tau' \)-majority \( x \) in more than one coalesced bitmap, as both areas should overlap on \([i, j] \) and then they would have been merged as a single area in \( A_x \). If we find one \( \tau' \)-majority in one coalesced bitmap, we know that there is a \( \tau' \)-majority \( x \) and can spot all of its occurrences (or the leftmost, if desired) in optimal time, even if we cannot know the identity of \( x \). Moreover, we will find all the distinct \( \tau' \)-majorities in this way.

### 4.3. Bounding the Number of Coalesced Bitmaps

This scheme will work well if we obtain just a few coalesced bitmaps overall. Next we show how to obtain only \( O((1/\tau) \log n) \) coalesced bitmaps.

**Lemma 5.** At most \( 2 \log_{1+\tau} n \) distinct values of \( x \) can have \( A_x[k] = 1 \) for a given \( k \).

**Proof.** First, \( A[k] = x \) is a \( \tau \)-majority in \( A[k], k \), thus \( A_x[k] = 1 \). Now consider any other element \( x' \neq x \) such that \( A_x'[k] = 1 \). This means that \( x' \) is a \( \tau \)-majority in some \([i, j] \) that contains \( k \). Since \( A[k] \neq x' \), it must be that \( x' \) is a \( \tau \)-majority in \([i, k-1] \) or in \([k+1, j] \) (or in both). We say \( x' \) is a left-majority in the first case and a right-majority in the second. Let us call \( y_1, y_2, \ldots \) the \( x' \) values that are left-majorities, and \( i_1, i_2, \ldots \) the starting points of their segments (if they are \( \tau \)-majorities in several segments covering \( k \), we choose one arbitrarily). Similarly, let \( z_1, z_2, \ldots \) be the \( x' \) values that are right-majorities, and \( j_1, j_2, \ldots \) the ending points of their segments. Assume the left-majorities are sorted by decreasing values of \( i \), and the right-majorities are sorted by increasing values of \( j \). If a same value \( x' \) appears in both lists, we arbitrarily remove one of them. As an exception, we will start both lists with \( y_0 = z_0 = x \), with \( i_0 = j_0 = k \).
It is easy to see by induction that $y_r$ must appear at least $(1 + \tau)^r$ times in the interval $[i_r, k]$ (or in $[i_r, k - 1]$, which is the same). This clearly holds for $y_0 = x$. Now, by the inductive hypothesis, values $y_0, y_1, \ldots, y_{r-1}$ appear at least $(1 + \tau)^0, (1 + \tau)^1, \ldots, (1 + \tau)^{r-1}$ times within $[i_{r-1}, k - 1]$ (which contains all the intervals), adding up to $\frac{(1+\tau)^r - 1}{\tau}$ occurrences. Thus $k - 1 - i_{r-1} + 1 \geq \frac{(1+\tau)^r - 1}{\tau}$. In order to be a left-majority, element $y_r$ must appear strictly more than $\tau(k - i_{r-1}) \geq (1 + \tau)^r - 1$ times in $[i_r, k - 1]$, to outweigh all the occurrences of the previous symbols. The case of right-majorities is analogous. This shows that there cannot be more than $\log_{1+\tau} n$ left-majorities and $\log_{1+\tau} n$ right-majorities.

In the following it will be useful to define $C_x$ as the set of maximal contiguous areas of 1s in $A_x$. That is, $C_x$ is obtained by merging all the segments of $S_x$ that touch or overlap. Note that segments of $C_x$ do not overlap, unlike those of $S_x$. Since a segment of $C_x$ covers a position $k$ iff some segment of $S_x$ covers position $k$ (and iff $A_x[k] = 1$), it follows by Lemma 5 that any position is covered by at most $2\log_{1+\tau} n$ segments of $C_x$ of distinct symbols $x$.

Note that a pair of consecutive positions $A[k] = x$ and $A[k+1] = y$ is also covered by at most $2\log_{1+\tau} n$ such segments: the right-majorities for $A[k]$ either are $y$ or are also right-majorities for $A[k+1]$, and those are already among the $\log_{1+\tau} n$ right-majorities of $A[k+1]$. And vice versa.

We obtain $O(\log_{1+\tau} n)$ coalesced bitmaps as follows. We take the union of all the sets $C_x$ of all the symbols $x$ and sort the segments by their starting points. Then we start filling coalesced bitmaps. We check if the current segment can be added to an existing bitmap without producing overlaps (and leaving a 0 in between). If we can, we choose any appropriate bitmap, otherwise we start a new bitmap. If at some point we need more than $2\log_{1+\tau} n$ bitmaps, it is because all the last segments of the current $2\log_{1+\tau} n$ bitmaps overlap either the starting point of the current segment or the previous position, a contradiction.

Example. We have $C_1 = \{[1, 1], [5, 7]\}$, $C_2 = \{[3, 3]\}$, and $C_3 = \{[1, 6]\}$. Now, we take $C_1 \cup C_2 \cup C_3 = \{[1, 1], [1, 6], [3, 3], [5, 7]\}$, and the process produces precisely the coalesced bitmaps $A'$, corresponding to the set $\{[1, 1], [3, 3], [5, 7]\}$, and $A_3$, corresponding to $\{[1, 6]\}$. 

Note that in general the coalesced bitmaps may not correspond to the union of complete original bitmaps $A_x$, but areas of a bitmap $A_x$ may end up in different coalesced bitmaps.

Therefore, the coalescing process produces $O(\log_{1+\tau} n) = O((1/\tau) \log n)$ bitmaps. Consequently, we obtain $O((1/\tau) \log n)$ query time by simply checking the coalesced bitmaps one by one using Lemma 3.

Finally, representing the $O((1/\tau) \log n)$ coalesced bitmaps $A'$, which have total length $O((n/\tau) \log n)$ and contain $O(n/\tau)$ 1s, requires $O((n/\tau) \log \log n)$ bits if we use a compressed bitmap representation [25] that still offers constant-time rank and select queries (recall Section 2.2). The coalesced bitmaps $M'$ still have total length $O(n/\tau)$.
This completes the first part of our result. Next, we will reduce the space usage of our encoding.

5. Reducing the Space to $O(n \log(1/\tau))$ Bits

We introduce a different representation of the coalesced bitmaps that allows us to store them in $O(n \log(1/\tau))$ bits, while retaining the same mechanism described above. We note that, although there can be $O(n/\tau)$ bits set in the bitmaps $A_x$, each new element $x$ produces at most one new run of contiguous 1s (case (1) in the proof of Lemma 4). Therefore there are at most $n$ runs in total. We will use a representation of coalesced bitmaps that takes advantage of these runs.

We will distinguish segments of $C_x$ by their lengths, separating lengths by ranges between $[2^\ell/\tau]$ and $[2^{\ell+1}/\tau] − 1$, for any level $0 ≤ \ell ≤ \log(\tau n)$ (level 0 is special in that it contains lengths starting from 1). In the process of creating the coalesced bitmaps described in the previous section, we will have separate coalesced bitmaps for inserting segments within each range of lengths; these will be called bitmaps of level $\ell$. There may be several bitmaps of the same level. It is important that, even with this restriction, our coalescing process will still generate $O((1/\tau) \log n)$ bitmaps, because only $O(1/\tau)$ coalesced bitmaps of each level $\ell$ will be generated.

**Lemma 6.** There can be at most $4/\tau$ segments of any $C_x$, of length between $[2^\ell/\tau]$ and $[2^{\ell+1}/\tau] − 1$, covering a given position $k$, for any $\ell$.

Proof. Any such segment must be contained in the area $A[k − [2^{\ell+1}/\tau] + 1, k + [2^{\ell+1}/\tau] − 1]$, and if $x$ is a $\tau$-majority in it, it must appear more than $\tau [2^\ell/\tau] ≥ 2^\ell$ times. There can be at most $4/\tau$ different values of $x$ appearing more than $2^\ell$ times in an area of length less than $2^{\ell+2}/\tau$. □

Consider a coalesced bitmap $A'[1,n]$ of level $\ell$. All of its 1s come in runs of lengths at least $b = [2^\ell/\tau]$. We cut $A'$ into chunks of length $b$ and define two bitmaps: $A'_1[1,n/b]$ will have $A'_1[i] = 1$ iff the $i$th chunk of $A'$ is all 1s, and $A'_2[1,n/b]$ will have $A'_2[i] = 1$ iff the $i$th chunk of $A'$ has 0s and 1s. Note that, since the runs of 1s are of length at least $b$, inside a chunk with 0s and 1s there can be at most one 01 and at most one 10, and the 10 can only come before the 01. Let $p_10[j]$ be the position, in the $j$th chunk with 0s and 1s, of the 1 preceding a 0, where $p_10[j] = 0$ if the chunk starts with a 0. Similarly, let $p_01[j]$ be the position of the 0 preceding a 1, with $p_01[j] = b$ if the chunk ends with a 0. It always holds that $p_10[j] < p_01[j]$, and the number of 1s in the chunk is $r(j) = p_10[j] + (b − p_01[j])$. Also, the rank up to position $k$ in the chunk, $r(j,k)$, is $k$ if $k ≤ p_10[j]$, $p_10[j]$ if $p_10[j] < k ≤ p_01[j]$, and $p_10[j] + (k − p_01[j])$ if $k > p_01[j]$. Then it holds that

$$\text{rank}(A', i) = b \cdot r_1 + \sum_{j=1}^{r_2} r(j) + \begin{cases} r(r_2 + 1, k) \text{ if } A'_2[1 + \lfloor i/b \rfloor] = 1 & \text{else } A'_2[1 + \lfloor i/b \rfloor] \cdot k, \end{cases}$$

12
Construction

Construction sets constructed in $O(n \log(n/\tau) \log \log(n/\tau))$ time, using plain rank/select structures \cite{18, 8}, or even using $O(n \log(1/\tau) + (n/\tau)/\text{polylog } n)$ bits, for any polylog $n$, using compressed representations \cite{24}. The extra $O(\log \log_w(1/\tau))$ time factor arises when we insist in obtaining the optimal $O(n \log(1/\tau))$ bit space. We note that this time penalty factor vanishes when $1/\tau = w^{O(1)}$, which includes the case where $1/\tau$ grows polylogarithmically with $n$.

6. Construction

The most complex part of the construction of our encoding is to build the sets $C_x$. Once these are built, the structures described in Section 5 can be easily constructed in $o(n \log n)$ time:
1. The $O(n)$ segments $C_x$ belong to $[1, n]$, so they are sorted by starting point in $O(n)$ time.

2. We maintain a priority queue for each level $\ell$, containing the last segment of each coalesced bitmap. We use the queue to find the segment that finishes earliest in order to try to add the new segment of $C_x$ after it. We carry out, in total, $O(n)$ operations on those queues, and each contains $O(1/\tau)$ elements, thus they take total time $O(n \log(1/\tau)) = o(n \log n)$.

3. The bitmaps $A'$ of each level $\ell$, represented with $A'_{11}$, $A'_{22}$, $A'_{01}$ and $A'_{10}$, are easily built in $O(n/b) = O(n\tau/2^\ell)$ time. Added over the $O(1/\tau)$ coalesced bitmaps of level $\ell$ this is $O(n/2^\ell)$, and added over all the levels $\ell$ this gives $O(n)$ total time.

4. The coalesced bitmaps $M'$ have $O(n)$ 1s overall, so their representation (Lemma 1) is also built in $O(n)$ time, except for the predecessor structures, which need construction of deterministic dictionaries. This can be done in $o(n \log n)$ total time $[20]$.

Now we show that the sets $C_x$ can be built in $O(n \log n)$ time, thus finishing the proof of Theorem 2.

We build the set of increasing positions $P_x$ where $x$ appears in $A$, for each $x$, in $O(n \log n)$ total time (the elements of $A$ can be of any atomic type, so we only rely on a comparison-based dictionary to maintain the set of different $x$ values and their $P_x$ lists). Now we build $C_x$ from each $P_x$ using a divide-and-conquer approach, in $O(|P_x| \log |P_x|)$ time, for a total construction time of $O(n \log n)$.

We pick the middle element $k \in P_x$ and compute in linear time the segment $[l, r] \in C_x$ that contains $k$. To compute $l$, we find the leftmost element $p_l \in P_x$ such that $x$ is a $\tau$-majority in $[p_l, k_r]$, for some $k_r \in P_x$ with $k_r \geq k$.

To find $p_l$, we note that it must hold that $(w(p_l, k - 1) + w(k, k_r))/(k_r - p_l + 1) > \tau$, where $w(i, j)$ is the number of occurrences of $x$ in $A[i,j]$. The condition is equivalent to $w(p_l, k - 1)/\tau + p_l - 1 > k_r - w(k, k_r)/\tau$. Thus we compute in linear time the minimum value $v$ of $k_r - w(k, k_r)/\tau$ over all those $k_r \in P_x$ to the right of $k$, and then traverse all those $p_l \in P_x$ to the left of $k$, left to right, to find the first one that satisfies $w(p_l, k - 1)/\tau + p_l + 1 > v$, also in linear time.

Once we find the proper $p_l$ and its corresponding $k_r$, the starting position of the segment is slightly adjusted to the left of $p_l$, to be the smallest value that satisfies $w(p_l, k_r)/(k_r - l + 1) > \tau$, that is, $l$ satisfies $l > -w(p_l, k_r)/\tau + k_r + 1$, or $l = k_r - \lceil w(p_l, k_r)/\tau \rceil + 2$.

Once $p_r$ and then $r$ are computed analogously, we insert $[l, r]$ into $C_x$ and continue recursively with the elements of $P_x$ to the left of $p_l$ and to the right of $p_r$. Upon return, it might be necessary to join $[l, r]$ with the rightmost segment of the left part and/or with the leftmost segment of the right part, in constant time. The total construction time is $T(n) = O(n) + 2T(n/2) = O(n \log n)$.

Building multiple structures. In order to answer $\tau'$-majority queries for any $\tau \leq \tau' < 1$ in time related to $1/\tau'$ and not to $1/\tau$, we build the encoding of Theorem 2 for values $\tau'' = 1/2, 1/4, 1/8, \ldots, 1/2^{\lfloor s/\tau \rfloor}$. Then, a $\tau'$-majority query is run
on the structure built for $\tau'' = 1/2^{\lfloor \log 1/\tau' \rfloor}$. Since $\tau'/2 < \tau'' \leq \tau'$, the query time is $O((1/\tau'') \log \log_w (1/\tau'') \log n) = O((1/\tau') \log \log_w (1/\tau') \log n)$.

As for the space, we build $O(\log(1/\tau))$ structures, so we use $O(n \log^2 (1/\tau))$ bits, and the construction time is $O(n \log(1/\tau) \log n)$.

**Corollary 1.** Given a real number $0 < \tau < 1$, there exists an encoding using $O(n \log^2 (1/\tau))$ bits that answers range $\tau'$-majority queries, for any $\tau \leq \tau' < 1$, in time $O((1/\tau') \log \log_w (1/\tau') \log n)$, where $w = \Omega(\log n)$ is the RAM word size in bits. The structure can be built in time $O(n \log(1/\tau) \log n)$.

### 7. A Faster Data Structure

In this section we show how, by adding $O(n \log \log n)$ bits to our data structure, we can slash a log $n$ factor from the query time, that is, we prove Theorem 3. The result, as discussed in the Introduction, yields the optimal query time $O(1/\tau)$ when $1/\tau = O(\text{polylog } n)$, although the resulting space may not be optimal anymore.

The idea is inspired in a previous non-encoding data structure for majority queries [1]. Consider a value $x$. Then we will cut $A$ into consecutive pieces of length $2^\ell$ (said to be of level $\ell$) in two overlapped ways: $A[2^\ell k + 1, 2^\ell (k + 1)]$ and $A[2^\ell k + 2^{\ell-1} + 1, 2^\ell (k + 1) + 2^{\ell-1}]$, for all $k \geq 0$. We carry out this partitioning for every $[\lfloor \log (1/\tau) \rfloor \leq \ell \leq \lceil \log n \rceil]$.

Note that there are $O(n/2^\ell)$ pieces of level $\ell$, and any interval $A[i, j]$ of length up to $2^\ell / 2$ is contained in some piece $P$ of level $\ell$. Now, given a query interval $A[i, j]$, let $\ell = \lceil \log (j - i + 1) \rceil + 1$. Then, not only $A[i, j]$ is contained in a piece $P$ of level $\ell$, but also any $\tau$-majority $x$ in $A[i, j]$ must be a $\tau$/4-majority in $P$. If $j - i + 1 > 2^\ell / 4$, $x$ occurs more than $\tau (j - i + 1) > (\tau/4)2^\ell$ times in $A[i, j]$, and thus in $P$.

Consider a $\tau$/4-majority $x$ in a given piece $P$ of level $\ell$ that is also a $\tau$-majority for some range $A[i, j]$ within $P$, where $2^\ell / 4 < j - i + 1 \leq 2^\ell / 2$. By construction of our previous structures, there exists a maximal segment $C_x$ that contains the range $[i, j]$. If there is another range $A[i', j']$ within $P$ where $x$ is a $\tau$-majority, then there exists another maximal segment $C'_x$ for the same $x$ within $P$. By our construction, if $C_x' \neq C_x$, then $C_x''$ is disjoint with $C_x$, and thus each of them contains at least $(\tau/4)2^\ell$ distinct occurrences of $x$. Obviously, segments $C_y$ for $\tau$-majorities $y \neq x$ contain other $(\tau/4)2^\ell$ occurrences disjoint from those of $x$. Therefore, the number of distinct maximal segments $C$ that contain $\tau$-majorities at any range $A[i, j]$ within $P$ is upper bounded by $4/\tau$. We will say those segments $C$ are relevant to $P$.

Therefore, for each piece $P$ of level $\ell$, we will store the index $r$ of the coalesced bitmap $A_r'$ (and its companion $M'_r$) to which each maximal segment $C$ that is relevant to $P$ belongs. Since there are at most $4/\tau$ such coalesced bitmaps to record, out of a total of $O((1/\tau) \log n)$ coalesced bitmaps, $\gamma$-codes on a differential encoding of the subset values requires $O((1/\tau) \log \log n)$.
further bits, and allows checking only one coalesced bitmap 

A structure (for short ranges) is easily built with the general structure, taking 

no additional time, by keeping track of which maximal segment 

in a piece 

structure for long ranges can be built as follows: for each position 

where the maximal segment 

A 

is relevant to 

k 

that contains the segment 

A[k, k] belongs, and 

store the identifier 

r of the corresponding coalesced bitmap 

A′ and 

M′ associated to 

k. This requires 

O(n log((1/τ) log n)) = O(n log(1/τ) + n log log n) 

further bits, and allows checking only one coalesced bitmap 

A′ and 

M′ for each of the 

O(1/τ) positions that need to be checked.

To finish the proof we must consider the construction time. The second structure (for short ranges) is easily built with the general structure, taking 

no additional time, by keeping track of which maximal segment 

C_{A[k]} containing the segment 

A[k, k] belongs, and 

store the identifier 

r of the corresponding coalesced bitmap 

A′ and 

M′ associated to 

k. This requires 

O(n log((1/τ) log n)) = O(n log(1/τ) + n log log n) 

further bits, and allows checking only one coalesced bitmap 

A′ and 

M′ for each of the 

O(1/τ) positions that need to be checked.

The rank operations on bitmaps 

M take 

O(\log \log_w(1/τ)) time, so we avoid them to count how many 1s does 

M′ contain in the range of 

P. Instead, we perform a preprocessing pass over 

P as follows: We initialize to zero a set of 

O((1/τ) \log n) counters, one per coalesced bitmap 

M′, and process 

P left to right. We increase the counter associated to the bitmap 

M′ of each element 

A[k] in 

P. At the end, we know all the desired values. This takes 

O(2^ℓ) time, and a similar postprocessing pass clears the counter for the next piece.

Therefore, we process all the pieces 

P of level 

ℓ in time 

O(2^ℓ), which amounts to 

O(n) time per level. Added over all the levels, this gives 

O(n \log n) total time. This concludes the proof of Theorem 8.

8. Conclusions

A τ-majority query on array 

A[1, n] receives a range 

[i, j] and returns all the elements appearing more than 

τ(j − i + 1) times in 

A[i, j]. We have obtained the first results about encodings for answering range τ-majority queries. Encodings are data structures that use less space than what is required to store 

A and

~\footnote{We could also afford to store them in plain form using \( O((1/τ)(\log(1/τ) + \log \log n)) \) bits.}
answer queries without accessing $A$ at all. In the encoding scenario we do not report the $\tau$-majorities themselves, but one of their positions in $A[i,j]$.

We have proved that $\Omega(n \log(1/\tau))$ bits are necessary for any such encoding, even if it can only count the number of $\tau$-majorities in any range. Then we presented an encoding that uses the optimal $O(n \log(1/\tau))$ bits, and answers queries in $O((1/\tau) \log \log_w (1/\tau) \log n)$ time in the RAM model with word size $w = \Omega(\log n)$ bits. We also showed that this time can be divided by $\log n$ if we add $O(n \log \log n)$ bits to the space. This yields various space/time tradeoffs, shown in Table 1. Our encoding can actually report any occurrence of each $\tau$-majority, in optimal extra time. The structure is built in $O(n \log n)$ time.

An open question is whether it is possible to achieve optimal query time within optimal space for all values of $1/\tau$. As seen in Table 1, we reach this only for $\log(1/\tau) = \Theta(\log \log n)$. This is also possible when $\log(1/\tau) = \Omega(\log n)$, where we leave the non-encoding scenario [1]. Instead, our results for $\log(1/\tau)$ between $\log \log n$ and $\log n$ have a small factor $O(\log \log_w(1/\tau))$ over the optimal time, and those for $\log(1/\tau)$ below $\log \log n$ either require nonoptimal $O(n \log \log n)$ bits of space, or an $O(\log n)$ factor over the optimal time. It is not clear whether combined optimality can be reached.

Another open question is whether we can do better for weaker versions of the problem we have not studied. For example, if we are only required to report any occurrence of any $\tau$-majority (or, even less, telling whether or not there exists a $\tau$-majority), our lower bound based on representing a bitmap $B$ shows that $\Omega(n)$ bits are necessary, but we do not know if this bound is tight.
