**Keywords:**
- Amphotericin B
- Clear corneal tunnel infection
- Fungal endophthalmitis
- Intravitreal antifungals
- Voriconazole

**A B S T R A C T**

**Purpose:** To describe a patient with late post-operative endophthalmitis and clear cornea tunnel infection caused by *Candida parapsilosis* that was masquerading as chronic anterior uveitis.

**Observations:** A 62-year old woman with history of uncomplicated cataract surgery 7 months prior and chronic postoperative anterior uveitis, presented with an endothelial plaque, hypopyon, and infiltrates in the capsular bag and within the clear corneal tunnel. Anterior chamber cultures identified *C. parapsilosis* and pathology of the endothelial plaque showed fungus. Anterior chamber washout, scraping of the endothelial plaque, serial intracameral and intravitreal injections with amphotericin B (10 mcg) failed to control the infection. Pars plana vitrectomy, removal of the intraocular lens and capsular bag, a corneal patch graft, and administration of intravitreal antifungal agents were performed. One year later the patient remains free of recurrence and her best-corrected vision is 20/25 with a rigid gas permeable contact lens.

**Conclusions:** and Importance: Persistent intraocular and intracorneal inflammation after cataract surgery should raise suspicion of endophthalmitis caused by fungi non-responsive to topical and intravitreal antibiotics. Surgical intervention and removal of the nidus of infection, which is often the intraocular lens and capsular bag, may be necessary for a successful outcome.

1. Introduction

*Candida parapsilosis* has emerged as an opportunistic fungal pathogen over the last two decades especially in debilitated patients and low birth weight neonates.1 Though typically a commensal of human skin, its capacity to form biofilms on catheters and implants accounts for its increased incidence within the nosocomial setting.2 *Candida parapsilosis* is a well-known cause of delayed-onset postoperative endophthalmitis with at least 3 epidemics in the mid-1980s due to contaminated irrigating solutions used intraoperatively.3–5 It has also been described as the causative organism for suppurrative fungal keratitis and crystalline keratopathy after corneal transplantation,6,7 laser in situ keratomileusis (LASIK),8 insertion of intracorneal ring segments,9 treatment of epithelial ingrowth post-LASIK,10 trauma with vegetable matter,11 and Boston type 1 keratoprosthesis implantation.12

Herein, a case of *Candida parapsilosis* cornea tunnel infection with late-onset endophthalmitis is reported after cataract surgery via phacoemulsification and all similar cases in the literature of fungal tunnel infections post-cataract surgery are reviewed.

2. Findings

A 62-year old female self-referred to the Bascom Palmer Eye Institute (BPEI) Emergency Department for further management of chronic postoperative anterior uveitis in her left eye. The patient had history of uncomplicated cataract surgery with insertion of a posterior chamber intraocular lens (IOL) 7 months prior to presentation. She had been treated with topical difluprednate 0.05% and bromfenac 0.07% eye drops for recurrent inflammation in the anterior chamber. At least 3 attempts were made by her surgeon and an outside retina specialist to taper her anti-inflammatory regimen without success. Past medical history did not reveal other predisposing factors or increased risks for developing a Candida infection. An extensive uveitis work-up, which included a complete blood count, sedimentation rate, Quantiferon gold test, chest X-ray, rapid plasma reagin (RPR), fluorescent treponemal antibody (FTA-ABS), angiotensin converting enzyme, serum lysozyme, anti-nuclear antibody (ANA), toxoplasmosis IgM and IgG antibodies, HLA B27 antigen, HLA B51 antigen and Lyme titers, was performed and was negative.

Two weeks prior to presentation to us she experienced increased
redness and light sensitivity. Her outside retina specialist noted new keratic precipitates, 1+ cell in the anterior chamber, a new infiltrate along the clear cornea cataract incision tract and new focal deposits on the posterior surface of the IOL and inside the capsular bag. Given the concern for chronic postoperative endophthalmitis, an anterior chamber culture was sent by her outside physician and vancomycin and moxifloxacin were injected intracameraly and ceftazidime was injected intravitreally. On postoperative day 3, the patient experienced recurrence of the anterior chamber inflammation and reported to BPEI for further management.

Upon presentation to us, her left eye had mild perilimbal injection, a noticeable infiltrate along the clear cornea cataract tunnel temporally, a small hypopyon and endothelial plaque inferiorly, and white fluffy-appearing deposits between the IOL and the capsular bag temporally (Fig. 1). There was no vitritis and her vision was 20/50. At this time, the anterior chamber cultures from the outside medical center came back positive for *Candida*. A repeat anterior chamber washout and cultures, scraping of the endothelial plaque and injections of intracameral and intravitreal amphotericin B (0.2 mL of 5 mcg/0.1 mL) were performed. She was also started on hourly topical amphotericin B 0.5 mg/mL drops and topical steroids were stopped. Cultures showed *C. parapsilosis* and pathology of the endothelial plaque that was removed revealed fungal elements.

Despite a repeat intracameral amphotericin B injection 3 days after the anterior chamber washout, the hypopyon, capsular/IOL deposits and intrastromal wound infiltrate persisted (Fig. 2). Thus, 7 days after the washout at BPEI, the patient was brought back to the operating room for definitive surgical management of the *C. parapsilosis* endophthalmitis. A 23-gauge pars plana vitrectomy was performed, the IOL and the capsular bag were removed in toto through a superior 7 mm long scleral tunnel incision 2 mm posterior to the limbus and a 6.5 mm corneal patch graft was performed temporally at the site of the prior cataract wound. The patient was left aphakic and intravitreal voriconazole (0.2 mL of 100 mcg/0.1 mL) and amphotericin B (0.2 mL of 5 mcg/0.1 mL) were injected at the end of the procedure. In view of persistent ocular infection despite prior treatment with intravitreal amphotericin-B, a combination approach was utilized at the time of the definitive surgical procedure. Her post-operative regimen included topical amphotericin B 0.5 mg/mL, voriconazole 1% and cyclosporine 0.5% drops which were slowly tapered (Fig. 3). Histopathology examination revealed budding yeast along the cornea tunnel (Fig. 4A) and within the capsular bag (Fig. 4B). At her 1-year follow up visit her best-corrected vision in that eye is 20/25 with a rigid gas permeable lens and she remains free of recurrence (Fig. 5).

### 3. Discussion

*Candida* endophthalmitis after cataract surgery typically has a
delayed-onset presentation, as it is often masked by a favorable response to the frequent steroid use immediately after surgery. Candida species is well known for its tendency to form biofilms and, thus, successful treatment of the infection often requires removal of the IOL/capsular bag complex along with pars plana vitrectomy and intravitreal antifungals.13

Fungal corneal tunnel infections after phacoemulsification cataract surgery are rare with only 23 cases having been reported in the literature (Table 1).14–29 Twelve eyes (52.2%) progressed to endophthalmitis with poor visual outcomes (visual acuity ≤20/400) in 3 patients and loss of the eye in 4 patients (3 became phthisical and one underwent evisceration). In 14 of the 23 cases (60.9%) the main incision was clear corneal and in 9 (39.1%) it was sclerocorneal. The latency period between the date of the cataract surgery and the presentation of the fungal tunnel infection ranged from 3 days to 15 years (median, 30 days). Most infections were caused by Aspergillus spp. (n = 12, 52.2%), two by Fusarium spp. (8.7%), two by Alternaria spp. (8.7%), two by Candida albicans (8.7%), one by Candida parapsilosis (4.3%), one by Scedosporium apiospermum (4.3%) and one by Phialemonium curvatum (4.3%). In two (9.1%) of the reported cases the fungal elements were seen on smear, but the organisms did not grow on culture media.

The current patient represents the second case reported in the literature of C. parapsilosis cornea tunnel infection complicated by endophthalmitis. The first case, reported by Gregori et al., in 2007, also failed medical management with intravitreal amphotericin B and pars plana vitrectomy with removal of the IOL/capsular bag complex and therapeutic penetrating keratoplasty were required.25 The final visual acuity for that patient was 20/400. The two cases of tunnel infections caused by the related species C. albicans did not result in endophthalmitis and were treated with topical and oral antifungals (Table 1).

In total, in 10 (43.5%) fungal tunnel infections, medical management with topical, intraocular and systemic antifungals failed to control the infection, thus a sclerocorneal patch graft or therapeutic penetrating keratoplasty was performed and it was combined with pars plana vitrectomy in 3 of them. Two patients refused surgery upon failure of medical management of the infection and both of those eyes became phthisical. The mean best-corrected vision for all cases with a fungal tunnel infection was 20/400 and the median was 20/100.

This patient remains free of recurrence 1 year after the combined cornea IOL/capsular bag explantation and retina surgery. Current visual acuity corrects to 20/25 with a rigid gas permeable lens. In this patient, management of combined fungal cornea tunnel infection and endophthalmitis was successful after removal of all possible infectious niches and the long-term outcome was favorable.

4. Conclusions

Fungal tunnel infections after phacoemulsification cataract surgery are not common, yet when they result in fungal late-onset endophthalmitis, management can be challenging. The goal is to eradicate any source of infection within the eye and in the cornea. Medical management alone (with topical, intraocular, and systemic antifungals) often fails to control the infection and a combined surgical approach can be pursued to remove the IOL/capsular bag and to replace the infected corneal stroma with a healthy graft.

Patient consent

Consent to publish was not obtained. This report does not contain any personal information that could lead to identification of the patient.

PKP, penetrating keratoplasty; IOL, intraocular lens; PPV – pars plana vitrectomy; BCVA – best corrected visual acuity.

* In these cases, topical, intracameral and systemic antifungals ± anterior chamber washout was not curative. Fungal infiltrates recurred along the cornea tunnel. Thus, a tectonic (patch) graft ± pars plana vitrectomy was performed.

* In these cases, the infection progressed to endophthalmitis despite medical management. Therapeutic penetrating keratoplasty with IOL explantation, pars plana vitrectomy and injection of intravitreal antifungals was advised, but the patients refused. Eventually, these eyes became phthisical.
