The identification of cosmic objects emitting high energy neutrinos could provide new insights about the Universe and its active sources. The existence of these cosmic neutrinos has been proven by the IceCube collaboration, but the big question of which sources these neutrinos originate from, remains unanswered. The KM3NeT detector for Astroparticle Research with Cosmics in the Abyss (ARCA), with a cubic kilometer instrumented volume, is currently being built in the Mediterranean Sea. It will excel at identifying cosmic neutrino sources due to its unprecedented angular resolution for muon neutrinos ($< 0.2^\circ$ for $E > 10\,\text{TeV}$ neutrinos). KM3NeT has a view of the sky complementary to IceCube, and is sensitive to neutrinos across a wide range of energies. In order to identify the signature of cosmic neutrino sources in the background of atmospheric neutrinos and muons, statistical methods are being developed and tested with Monte-Carlo pseudo-experiments. This contribution presents the most recent sensitivity estimates for diffuse, point-like and extended neutrino sources with KM3NeT/ARCA.

*Presenter
1. Introduction

In 2013, the IceCube Neutrino Observatory confirmed the existence of a high-energy astrophysical neutrino flux [1]. However, the origin of most of these neutrinos remains unknown. The KM3NeT/ARCA detector [2] that is currently under construction at the bottom of the Mediterranean Sea, will consist of 2 building blocks, each consisting of 115 lines with 18 digital optical modules per line. It will have an excellent pointing resolution (< 0.2° for \(E > 10\) TeV muon neutrinos), it will be sensitive in a large energy range (GeV - PeV), with a sky coverage with upgoing neutrinos complementary to the IceCube detector that includes the galactic centre.

In order to identify a cosmic neutrino signal on top of the atmospheric background of muons and neutrinos, statistical methods are being developed based on Monte Carlo pseudo experiments. Compared to previously published work [3], the new methods presented here are the start of a bigger software framework for all future high energy astrophysical analysis. After applying the right cuts to increase the signal to background ratio, the detector response functions are determined. These distributions, like the so called effective area, the energy resolution and angular resolution are converted to probability density functions and are used as an input for the unbinned likelihood analysis to calculate the expected sensitivity of KM3NeT/ARCA to diffuse, point source and extended sources in our universe. The methods, and results will be presented in this contribution.

2. Method

2.1 Simulations used

The analysis is based on GENHEN (version v7r6) [4] Monte Carlo data simulations of \(10^2 \rightarrow 10^8\) GeV neutrino interactions for the KM3NeT/ARCA detector. Neutrinos are weighted using either cosmic or atmospheric flux models. For the latter, the conventional flux of Honda(2006) [5] (with Gaider-H3a [6] knee-correction is used) is complemented by a prompt component parametrisation [7] with Gaider-H3a knee-correction. The \(\nu_\tau\) channel is currently not taken into account. Atmospheric muons are simulated by the Mupgage package (version v3r4he) [8]. Events are subjected to a full simulation of light generation and to the response of the detector, and are processed through the same trigger and track reconstruction algorithms that are foreseen for data.

2.2 Up-going and horizontal track selection

**Aim** The analysis uses tracks reconstructed as horizontal or upward going (\(\theta < 100^\circ\)). A first set of well-reconstructed events are selected using requirements on, amongst others, reconstruction likelihood and the angular error estimate. On the events that are not selected a boosted decision tree (BDT) is applied. Events with a high BDT score are added to the sample as well. The BDT was trained using 20 variables related to the reconstructed track. Because the background contribution is larger for horizontal tracks, two different values are chosen to apply the cut for up-going (BDT > 0) and horizontal tracks (BDT > 0.7).

**Performance** The overall performance of the selection as described in this section is presented in table 1 and figures 1, and 2. Table 1 shows the number of events with up-going and horizontal
Sensitivity estimates for diffuse, point-like and extended neutrino sources with KM3NeT/ARCA, R.S. Muller

|                  | Zenith cut | Total  |
|------------------|------------|--------|
| muons            | all        | 208685.6 | 249.5 |
| conv. $\nu$      | all        | 54012.4  | 42744.4 |
|                  | +w/ muon   | 49937.4  | 42687.7 |
|                  | $+\alpha < 10^\circ$ | 43480.8  | 41454.4 |
| prompt $\nu$     | all        | 225.3    | 128.5  |
|                  | +w/ muon   | 147.9    | 127.6  |
|                  | $+\alpha < 10^\circ$ | 129.3    | 124.4  |
| cosmic $\nu$     | all        | 158.7    | 99.4   |
|                  | +w/ muon   | 113.5    | 98.6   |
|                  | $+\alpha < 10^\circ$ | 101.2    | 97.0   |

**Table 1**: Number of expected events for one year of operation with one building block after selecting events with horizontal or up-going tracks (third column) and passing the overall selection (fourth column).

**tracks, and those events that fulfill the signal-like criteria, or survive the BDT cut**. The final sample contains both these type of events.

The neutrino purity ($P$) of the final sample = \(\frac{\text{number of selected neutrino events}}{\text{number of selected events}} = 99.4\%\), of which 99.9\% are $\nu_\mu$. The signal efficiency ($\epsilon$) = \(\frac{\text{number of selected signal events}}{\text{number of signal events with up-going or horizontal tracks}}\) is computed for each neutrino component independently as a function of the neutrino energy. Overall the efficiency for well reconstructed tracks is above 90\% and for events with muons in the detector above 80\%. One important feature of this selection is that the efficiency is almost identical for neutrino fluxes with very different shapes. Hence, the BDT selection will not be biased towards a certain cosmic flux assumption.

**Instrument response functions** From the selected event sample detector response functions are created, and are used as an input for the likelihood analysis. The detector response is assumed to be uniform in azimuth angle. Variations with zenith angle and energy (also in resolution) are taken into account.
3. Likelihood formalism

The analysis computes the extended maximum for the hypotheses with and without a cosmic neutrino source, to form the likelihood ratio as the optimal observable to test for the presence of a source. For this, a high-level description of the detector response is available in the form of tabulated (histogrammed) functions that describe the acceptance, the angular resolution and the performance of the energy estimate. Using the same probability density functions that are used to compute the event likelihoods, so-called pseudo-experiments (PE) can be generated. These represent full mock datasets of one or several years of real data.

The effective area as a function of energy ($E$) and declination ($\delta$) is computed by integrating over right ascension ($r$)

$$A_{c,f}^{\text{eff}}(E, \delta) = \frac{1}{2\pi} \int A_{c,f}^{\text{eff}}(E, \theta(\delta, r, t)) dr.$$  

This is used to compute the total rate of observed events for a given flux:

$$N^{\text{tot}}(\delta) = \sum_{f \text{ flavors}} \int dE A_{c,f}^{\text{eff}}(E, \delta) \Phi_f(E) T,$$

with $T$ the live time, and flavors refers here to $\nu_\mu$ and $\bar{\nu}_\mu$ (although the can accommodate other flavours in the future).

3.1 Point spread function

The point spread function is available as a distribution of the angle $\alpha$, i.e. the angle between the true neutrino direction and the reconstructed one, as function of the true energy $E$ and $\cos(\theta)$. Two different methods with compatible results have been developed to smear the detector PSF to account for the source extension (in this analysis: 'extended PSF'). The first method is based on the random samplings. Sampling $\alpha$ from the detector PSF function and $\phi_{PSF}$ in the range $[0, 2\pi]$ the reconstructed direction is build as $(\cos \phi_{PSF} \sin \alpha, \sin \phi_{PSF} \sin \alpha, \cos \alpha)$. The extended source

**Figure 2:** Left: Angular resolutions as function of the neutrino energy for $\nu_\mu$ CC events. Icecube resolution was extracted from the point source analysis [9]. Right: Effective area as function of the neutrino energy for the selected event sample. Icecube effective area was extracted from the diffuse analysis [10].
neutrino direction is build in the same way with $\phi_{\text{ext}}$ sampled in the range $[0, 2\pi]$ and $\psi$ sampled from the source extension function: either flat disk ($\psi = R^{1/2}$) or Gaussian ($\psi = R(-2 \ln r)^{1/2}$), where $r$ is a random number in a range $[0, 1]$ and $R$ is the source extension. The angle between the reconstructed direction and the extended source neutrino direction, $\xi$ is then calculated. The extended PSF as $\xi$ distribution is build doing $10^4$ realisations.

In the second method the analytic convolution between the detector PSF and the source extension is used. For dihedral angle $\phi = \phi_{\text{PSF}} - \phi_{\text{ext}}$ one can evaluate:

$$
cos \xi = \cos \alpha \cos \psi + \sin \alpha \sin \psi \cos \phi;
\frac{d\phi}{d\xi} = \frac{1}{\sqrt{1 - \cos \phi \sin \alpha \sin \psi}}.
$$

This allows convolution over two angles $\alpha, \psi$ as follows:

$$
P(\xi) = \int_0^\pi \int_{|\alpha - \xi|}^{|\alpha + \xi|} P(\alpha) d\alpha P(\psi) d\psi P(\phi) \frac{1}{\sqrt{1 - \cos \phi \sin \alpha \sin \psi}}.
$$

Note that the integration over $\psi$ angle is done in a reduced range since the triangle rule holds for $\alpha, \psi, \xi$ on a sphere.

### 3.2 Likelihood Function

The global likelihood maximised is given by

$$
\mathcal{L} = \sum_{i \in \text{events}} \sum_{k \in \text{components}} \log \left[ \frac{dN_{i,k}}{d\Omega d \log(E_{\text{rec}})} \right] - N_{\text{tot}},
$$

where the concept of component has been introduced, to denote a physical contribution to the event rate (such as background, a diffuse flux, or a point-source flux of neutrinos). $N_{\text{tot}}$ denotes the total number of expected events in all flavors, and all channels. The quantity in square brackets is the likelihood of each event $i$ for the component in question. For atmospheric neutrino background, it is taken directly from a distribution of $\theta$ and $E_{\text{rec}}$ obtained from simulations of the backgrounds, for the channel corresponding to event $i$. For a point-source component,

$$
\frac{dN_i}{d\Omega d \log(E_{\text{rec}})} = \sum_{f \in \text{flavors}} \int dE \frac{dP_f(\theta, \alpha)}{d\Omega d \log(E_{\text{rec}})} A_{\text{eff}}(E, \theta) \Phi_f(E).
$$

Here, for each event, the probability density function $P$ takes into account both the energy- and angular resolution, which are assumed to factorise.

### 3.3 Pseudo-experiment generation

Background events are generated by randomly drawing values of $E_{\text{rec}}$ and $\cos(\theta)$ from a 2-d distribution obtained with detailed simulations. For the generation of pseudo-experiments from a point-source, a 3-d histogram is produced, which contains the pdf of $\alpha$ and $E_{\text{rec}}$, and the time-of-day $\tau$. For a point source, the (sidereal) time-of-day uniquely determines the zenith angle (but not vise-versa). The histogram is filled by computing the zenith angle from $\tau$ and the source coordinates. For each $\tau$, the number of events as function of $E_{\text{rec}}$ and $\alpha$ then follows from Eq. 6. From the resulting distribution, events are drawn to be included as signal events in pseudo-experiments.
4. Results

The analysis tools described in the previous sections are used to evaluate the sensitivity of the KM3NeT detector to diffuse, point-like and extended neutrino sources with KM3NeT/ARCA. Here our main results are presented.

Diffuse flux analysis In this section the sensitivity to characterise the astrophysical neutrino flux measured by IceCube’s diffuse analysis [17] is presented. To constrain the parameters associated with the flux model, confidence intervals will be constructed using the profile likelihood technique applying Wilks’ theorem.

The Asimov dataset [18] is generated assuming a nominal conventional flux, zero prompt flux and single power law spectra for the cosmic flux ($\Phi = 0.963 \cdot 10^{-6} E^{-2.37}$ [GeV$^{-1}$ cm$^{-2}$ s$^{-1}$ sr$^{-1}$]). Currently, three normalisation parameters ($\Phi_{\text{conv}}$, $\Phi_{\text{prompt}}$ and $\Phi_0$) and the spectral slope of the cosmic flux ($\gamma$) are fitted. Additional nuisance parameters associated with the systematic uncertainties on the atmospheric predictions or detector response are not incorporated yet.

In figure 3 the expected sensitivity of KM3NeT/ARCA is compared with the IceCube result assuming similar lifetimes. On the one hand, the narrower contours of this analysis are mainly due to the lack of systematic uncertainties. On the other hand, the more elongated shape is due to a different modelling of the prompt component in the IceCube analysis [16] and this analysis [7].

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure3.png}
\caption{Left: Two-dimensional confidence regions of the astrophysical parameters. Right: Neutrino spectra for the diffuse flux. Grey band represents the sensitivity estimates of the 68% confidence interval using 9.5 years of KM3NeT/ARCA (no systematics are included). The red band represents the best fit result from the IceCube analysis [17]. The black line is the conventional atmospheric neutrino flux prediction [5].}
\end{figure}

E$^{-2}$ point source analysis The sensitivity of KM3NeT to point sources with an E$^{-2}$ flux is analysed for different sky positions, and for 3, 7 and 7 years of data taking. Using the likelihood formalism, the source strength added to the background sample is varied between 0 and 20 events per year per building block. From the corresponding H1 distributions (4000 pseudo experiments), and the median of the H0 distribution (40,000 pseudo experiments) the number of signal events needed for a 90% CL exclusion is determined. The two flux normalisation parameters ($N_{\text{bkg}}, N_{\text{sig}}$) are fitted in the analysis. The spectral slope of the cosmic flux ($\gamma = 2$) is kept fixed. In figure 4 the results are shown in comparison to similar studies for 13 years of data taking with ANTARES (see ICRC poster contribution: poster 1142), and 7 years for IceCube [14].
Sensitivity estimates for diffuse, point-like and extended neutrino sources with KM3NeT/ARCA, R.S. Muller

Figure 4: Number of events (left) and flux normalisation (right) for 90% CL limits to detect a $E^{-2}$ point source with KM3NeT/ARCA in comparison with ANTARES 13 years (see ICRC poster contribution: poster 1142), and IceCube 7 years [14].

Figure 6: Left: Average upper limit at 90% CL. Right: Sensitivity at 90% CL.

Extended source analysis  The sensitivity of KM3NeT to the sources in table 2 is estimated. The prescriptions in [15] is implemented to derive the expected neutrino flux, as shown in figure 5.

| Source | Decl, RA [deg] | ext [deg] | Ref. |
|--------|----------------|-----------|------|
| RXJ 1713.7-3946 | -39.77 258.8 | 0.60 (disk) | [11] |
| HAWC J1825-134 | -13.37 276.4 | 0.53 (Gauss) | [12] |
| HAWC J2019+368 | 36.76 304.92 | 0.356 (Gauss) | [13] |
| HAWC J1907+063 | 6.32 286.91 | 0.67 (Gauss) | [12] |

Table 2: Gamma source parameters. The label \textit{disk/Gauss} is the assumed source morphology.

Figure 5: Expected neutrino fluxes of the sources (100% hadronic scenario is assumed).

The results are summarised in figure 6. This study demonstrates the capability of the KM3NeT detector to achieve a 90% CL sensitivity for 3 of the 4 considered sources in less than 4 years; for the most promising source (HAWC J1825-134) the sensitivity is achieved in approximately 1 year.
5. Conclusion and discussion

We have shown that our new likelihood method for KM3NeT to do high energy sensitivity studies for diffuse, point-like and extended neutrino source is in place, working, and providing convincing first results for KM3NeT/ARCA detector.
