The sensitivity of the rare decays $\eta^{(f)} \rightarrow \pi^0 \gamma \gamma$ and $\eta' \rightarrow \eta \gamma \gamma$ to signatures of a leptophobic $B$ boson in the MeV–GeV mass range is analyzed in this work. By adding an explicit $B$-boson resonance exchange, $\eta \rightarrow B \gamma \rightarrow \pi^0 \gamma \gamma$, to the Standard Model contributions from vector and scalar meson exchanges, and employing experimental data for the associated branching ratios, it allows us to improve the current constraints on the $B$-boson mass $m_B$ and coupling to Standard Model particles $\alpha_B$. From these constraints and the analysis of the available experimental $\gamma \gamma$ invariant mass distribution, we show that a $B$-boson signature in the resonant mass range $m_{\eta'} \lesssim m_B \lesssim m_{\eta}$ is strongly suppressed and would be very difficult to experimentally identify, assuming that the leptophobic $B$ boson only decays to Standard Model particles. In contrast, the limits outside this mass window are less stringent and the corresponding $t$- and $u$-channel signatures may still be observable in the data, as it occurs with the nonresonant Standard Model $\rho$, $\omega$, and $\phi$ meson exchanges. In addition, we make use of experimental data from the $\eta' \rightarrow \pi^0 \gamma \gamma$ and $\eta' \rightarrow \eta \gamma \gamma$ decays to explore larger $B$-boson masses. Our results are relevant for the $B$-boson search programs at existing and forthcoming light-meson facilities, such as KLOE-II and Jefferson Lab Eta Factory experiments.

Keywords: Chiral perturbation theory, meson decays, new physics

I. INTRODUCTION

An increasingly ubiquitous strategy to search for physical phenomena beyond the Standard Model (BSM) is to test fundamental symmetries such as $C$, $P$, $T$, $CP$, and $CPT$ in different processes. Specifically, decays of the neutral pseudoscalar mesons $\eta$ and $\eta'$ constitute a particularly suited playground to look for new physics [1, 2]. This is because these two mesons are special, as they are eigenstates of the fundamental symmetries such as $\eta$ and $\eta'$ decay sensitive hadronic probes to test discrete symmetries and to search for undiscovered fundamental BSM particles, such as dark photons or leptophobic $U(1)_B$ bosons (see Refs. [1, 2] and references therein).

Examples of these are the rare $\eta^{(f)} \rightarrow \pi^0 \gamma \gamma$ and $\eta' \rightarrow \eta \gamma \gamma$ decays which, as they are highly suppressed in the Standard Model (SM) [3–7], have been put forward as fine probes to search for new physics [1, 2]. This is because these two mesons are special, as they are eigenstates of the fundamental symmetries such as $\eta$ and $\eta'$ have placed constraints on the coupling for masses that span from below the MeV scale, obtained from long-range nuclear forces [14] and low-energy neutron scattering [15–17], to above the GeV scale, obtained at high-energy hadron colliders in dijet resonance searches, as well as in heavy quarkonia and $Z$ decays [18–23]. The intermediate MeV–GeV mass range has been less explored thus far [8, 10], which is down to this being the region of nonperturbative QCD, and has often been considered as a challenging blindspot for experiment in the past. However, searches for leptophobic $B$ bosons are gaining traction in this intermediate mass range given the potential signatures that can be looked for in decays of light mesons, such as $\eta$, $\eta'$, $\omega$, and $\phi$ [8], after years of sterile sub-GeV dark-photon searches most of them relying on direct photoproduction $\gamma p \rightarrow Bp \rightarrow \pi^+ \pi^- \pi^0 p$ at the GlueX experiment [35, 36], and is a top priority physics goal for the recently approved Jefferson Lab Eta Factory (JEF) experiment [37], which promises a new and exciting era for $\eta$ and $\eta'$ physics, with the $\eta \rightarrow \pi^0 \gamma \gamma$ decay being their key signal channel. The Belle Collaboration has also pursued searches for a $B$ boson decaying into $\pi^+ \pi^-$ using $\eta \rightarrow \pi^+ \pi^- \gamma$ decays [38] but have found no signal and, since $B \rightarrow \pi^+ \pi^-$ is suppressed by $G$-parity conservation, the limits on the $B$-boson parameters are not as stringent as the constraints coming from other decays, such as the $\eta \rightarrow \pi^0 \gamma \gamma$. B-boson searches may also be carried out at future $\eta/\eta'$ factories, such as the proposed REDTOP experiment [2], or in direct photoproduction $\gamma p \rightarrow Bp \rightarrow \pi^+ \pi^- \pi^0 p$ at the GlueX experiment at Jefferson Lab [39], which will probe $B$-boson masses above 0.5 GeV. Alternatively, signals of $U(1)_B$ leptophobic $B$ bosons decaying into invisible particles, i.e. dark photons could be detected.

‡ The current detector layout at REDTOP is nonsensitive to neutral final states [2], but an improved version of REDTOP is planned where the $\eta$ will be tagged and final states with $\pi^0$’s and photons could be detected.
matter, have also been pursued at neutrino factories [40] and at the LHC [41].

The model that we consider in this work for a $U(1)_B$ lepto-
phobic gauge boson $B$ that couples to the baryon number has the following interaction Lagrangian [8, 10]

$$\mathcal{L}_{\text{int}} = \left( \frac{1}{3} g_B + \epsilon \bar{Q}_c e \right) \bar{q} \gamma^\mu q B - \epsilon e \bar{e} \gamma^\mu \ell B_{\mu}, \quad (1)$$

where $B_{\mu}$ is the new gauge boson field and $g_B$ is the new gauge coupling, with $\alpha_B = g_B^2 / 4\pi$ being the fine structure constant associated to the baryonic force. This interaction structure is gauge invariant and preserves the low-energy symmetries of QCD, namely $C$, $P$ and $T$ invariance, as well as isospin and $SU(3)$-flavor symmetry.

Partial widths for $B$-boson decays in the MeV–GeV mass range have been calculated in [8] using the hidden local symmetry framework for vector meson dominance (VMD). Above the single-pion threshold, $m_{\pi^0} \lesssim m_B \lesssim 1$ GeV, the $B$ boson decays predominantly to $\pi^0\gamma$, or to $\rho^0\pi^+\pi^-$ when kinematically allowed, very much like the $\omega$ meson. In fact, the $B$ boson can be assigned the same quantum numbers as those from the $\omega$, i.e. $I^G(J^{PC}) = 0^-(1^{--})$. It must be noted that the interaction Lagrangian in Eq. (1) is not completely decoupled from leptons as it contains subleading photonlike couplings to leptons proportional to $\epsilon = g_B^2/(4\pi)^2$. This effect allows the purely leptonic decay $B \to e^+e^-$, which dominates below single-pion threshold $m_B \lesssim m_{\pi^0}$. There are other allowed decay channels such as $B \to \eta\gamma$ and $B \to \pi^+\pi^-$; however, these are subleading [8], where the latter, being forbidden by $G$-parity conservation, arises via $\rho-\omega$ mixing.

At present, conservative constraints from $\eta$ and $\eta'$ decays on the $B$-boson parameters $\alpha_B$ and $m_B$ are based on total rates setting the SM contribution to zero [8], i.e. assuming the $B$-boson intermediate states $\eta^{(i)} \to B\gamma \to \pi^0\gamma\gamma$, $\eta' \to B\gamma \to \pi^+\pi^-\pi^0\gamma$ and $\eta' \to B\gamma \to \eta\gamma\gamma$, and making use of the narrow width approximation (NWA), e.g. $BR(\eta \to \pi^0\gamma\gamma) = BR(\eta' \to B\gamma) \times BR(B \to \pi^0\gamma)$. It must be stressed, though, that the SM contribution to these decays is not negligible [5, 7, 42, 43] and, therefore, it should not be disregarded in exclusion analyses of $B$ bosons. Thus, one of the goals of the present work is to take into account SM effects in these analyses. To that effect, we employ our controlled SM contributions, i.e. the VMD and linear sigma model ($\sigma$M) amplitudes from Ref. [7], we supplement it with the explicit inclusion of an intermediate $B$ boson and use the most up-to-date experimental data.

Significantly greater sensitivity to the $B$-boson model could be obtained from the analysis of the invariant mass distributions. Provided that $m_{\pi^0} \leq m_B \leq m_{\eta^{(i)}}$, the $B$-boson mediated decay $\eta^{(i)} \to B\gamma \to \pi^0\gamma\gamma$ would reveal a peak at around $m_B$ in the $\pi^0\gamma$ invariant mass spectrum. Searches for a $\pi^0\gamma$ resonance within this mass region in $\eta \to \pi^0\gamma\gamma$ decays are the main physics goal of the JEF experiment [37], which plans to improve the total rate limit by two orders of magnitude, and is being searched for by KLOE-II via $\phi \to \eta B \to \eta \pi^0\gamma$ [35, 36] and $\eta \to B\gamma \to \pi^0\gamma\gamma$. Accordingly, we aim to perform a detailed analysis of the $\pi^0\gamma$ invariant mass distributions. In particular, using the available experimental diphoton spectra, together with our SM and $B$-boson amplitudes, we determine which regions of the $\alpha_B$-$m_B$ plane are preferred by the data and assess the $B$-boson contribution. It can be anticipated that, whilst the constraint from the $\eta \to \pi^0\gamma\gamma$ process in the resonant mass range $m_{\pi^0} \lesssim m_B \lesssim m_\eta$ is so strong that it makes it very difficult to identify any $B$-boson signatures (assuming that the $B$ boson only decays into SM particles), its imprint in the $t$ and $u$ channels may be noticeable in the invariant mass distributions when $m_B \lesssim m_{\pi^0}$ and $m_B \gtrsim m_\eta$, as it occurs with the nonresonant SM $\rho$, $\omega$ and $\phi$ exchanges [7]. Searches for lepto- phobic $B$ bosons require experimental precision, in order to disentangle their contribution from the SM, but also robust theoretical predictions. We attempt to undertake the latter in this work.

This article is structured as follows. In Sec. II A, we summarize the vector and scalar meson resonance exchange contributions to the amplitude for the three $\eta^{(i)} \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ decays [7]. In Sec. II B, we present the framework to include the contribution of intermediate $B$-boson exchanges to the amplitude. We then use the above amplitudes in Sec. III to, first, set limits on the $B$-boson parameters $\alpha_B$ and $m_B$ from the experimental branching ratios, and, second, to study the $B$-boson effect on the $\gamma\gamma$ and $\pi^0\gamma$ invariant mass spectra. We conclude this work with some conclusions in Sec. IV.

II. THEORETICAL FRAMEWORK

A. Standard Model: Vector and scalar contributions

VMD and the $\sigma$M can be used to calculate the SM contributions from vector and scalar meson resonance exchanges to the $\eta^{(i)} \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ decay processes. In Ref. [3], it was found that the VMD amplitude represents the dominant contribution to the $\eta \to \pi^0\gamma\gamma$ decay, whilst in [7] we showed that this is also the case for the $\eta' \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ processes.

In the VMD picture, the decay $\eta \to \pi^0\gamma\gamma$ proceeds through the transition $\eta \to V\gamma$ followed by $V \to \pi^0\gamma$, resulting in a total of six diagrams contributing to the amplitude of the process, which corresponds to the exchange of the three neutral vector mesons $V = \rho^0, \omega$ and $\phi$ in the $t$ and $u$ channels. By combining the $V\gamma\gamma$ and $V\pi^0\gamma$ interacting terms with the propagator of the exchanged vector mesons, one can calculate the vector meson contributions to the $\eta \to \pi^0\gamma\gamma$ decay. We found [7]

$$g_{\eta \to \pi^0\gamma\gamma} = \sum_{V=\rho^0, \omega, \phi} g_{V\gamma\gamma} g_{V\pi^0\gamma} \left[ \frac{(P \cdot q_2 - m_\pi^2)(a) - (b)}{D_V(t)} \right] \left\{ \frac{q_2 \leftrightarrow q_1}{t \leftrightarrow u} \right\}, \quad (2)$$
where $t, u = (P - q_1)^2 = m_\eta^2 - 2P \cdot q_1$ are Mandelstam variables, $\{a\}$ and $\{b\}$ are the Lorentz structures defined as

$$\{a\} = (\varepsilon_1 \cdot \varepsilon_2)(q_1 - q_2) - (\varepsilon_1 \cdot q_2)(\varepsilon_2 \cdot q_1),$$

$$\{b\} = (\varepsilon_1 \cdot q_2)(\varepsilon_2 \cdot P)(P \cdot q_1) + (\varepsilon_1 \cdot q_1)(\varepsilon_2 \cdot P)(P \cdot q_2) - (\varepsilon_1 \cdot \varepsilon_2)(P \cdot q_1)(P \cdot q_2) - (\varepsilon_1 \cdot \varepsilon_2)(P \cdot q_2)(q_1 \cdot q_2),$$

where $P$ is the four-momentum of the decaying $\eta$ meson, and $\varepsilon_{1,2}$ and $q_{1,2}$ are the polarization and four-momentum vectors of the final photons, respectively. The denominator $D_V(q^2) = m_V^2 - q^2 - im_V \Gamma_V$ is the vector meson propagator, with $V = \rho^0$, $\omega$ and $\phi$. Due to the fact that the $\rho^0$ meson has got a very large decay width, the use of the usual Breit-Wigner prescription is not justified and, thus, one is compelled to make use of an energy-dependent decay width

$$\Gamma_{\rho^0}(q^2) = \Gamma_{\rho^0}(\frac{q^2 - 4m_\eta^2}{m_{\rho^0}^2 - 4m_\eta^2})^{3/2}.$$  

The amplitudes for the decays $\eta' \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ have a similar structure to that of Eq. (2) with the replacements $m_\eta^2 \to m_{\eta'}^2$, and $g_{V\eta}\gamma g_{V\pi^0}\gamma \to g_{V\eta'\gamma}g_{V\pi^0\gamma}$ for the $\eta' \to \pi^0\gamma\gamma$ case and $g_{V\eta}\gamma g_{V\eta'}\gamma \to g_{V\eta'\gamma}g_{V\eta'\gamma}$ for the $\eta' \to \eta\gamma\gamma$ one.

For our analysis, we fix the $g_{VP\gamma}$ couplings in Eq. (2) from experiment as follows: we first calculate the decay widths for the radiative transitions $V \to P\gamma$ and $P \to V\gamma$, and find the following relationships

$$\Gamma_{V \to P\gamma} = \frac{1}{32\pi} \frac{g_{VP\gamma}^2}{m_V^2 - m_P^2} \left(\frac{m_V^2 - m_P^2}{m_P^2}\right)^3,$$

$$\Gamma_{P \to V\gamma} = \frac{g_{VP\gamma}^2}{32\pi} \left(\frac{m_V^2 - m_P^2}{m_P^2}\right)^3,$$

which then are used in combination with the experimental decay widths from the PDG [44] to obtain the empirical $g_{VP\gamma}$ couplings provided in Table I.

It is important to note that the most general $VP\gamma$ couplings in Eq. (2) are energy dependent, i.e. $g_{VP\gamma}(q^2)$. In the conventional VMD model, pseudoscalar mesons do not couple directly to photons but through the exchange of intermediate vectors; thus, in this framework, a particular $VP\gamma$ coupling constant times its normalized form factor is given by

$$g_{VP\gamma} \hat{F}_{VP\gamma}(q^2) = \sum_{\nu} g_{VV\nu} g_{VP\gamma} \frac{m_V^2}{m_{\nu}^2 - q^2},$$

where $g_{VV\nu}$ are the vector-vector-pseudoscalar couplings, $g_{VP\gamma}$ the vector-photon conversion couplings, and $m_{\nu}$ the intermediate vector masses. In the SU(3)-flavor symmetry and OZI-rule respecting limits, one could express all the $g_{VP\gamma}$ in terms of a single coupling constant $g$ and $SU(3)$-group factors [45]. On the other hand, in the context of resonance chiral theory (RChT), for instance, the $VP\gamma$ effective vertex is made of a local $VP\gamma$ vertex weighted by a coupling constant, $h_V$, and a nonlocal one built from the exchange of an intermediate vector weighted by a second coupling constant, $f_V$, times the vector-photon conversion factor $f_V$ [46]

$$g_{VP\gamma} \hat{F}_{VP\gamma}(q^2) = C_{VP\gamma} |e| 4\sqrt{2}h_V \frac{q^2}{m_V^2 - q^2},$$

where $C_{VP\gamma}$ are $SU(3)$-group factors. Notwithstanding this, and down to the fact that the outgoing photons in $\eta'(1) \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ are on shell, the energy dependence of the vertex form factors vanish in either model and the corresponding couplings become just constants [47]. As has just been explained, in the approach followed in the present work we extract the values for these coupling constants directly from experiment not relying on any specific model [45, 46], rendering our theoretical treatment of vector exchanges rather model independent.

Moving on to the effects of scalar resonance exchanges on the decays under study, they were explicitly assessed in Ref. [7] making use of the LoSM and it was found that the scalar contributions are subdominant, whilst the exchange of vector resonances largely dominate. Accordingly, it has been deemed not necessary to employ a more sophisticated theoretical treatment, such as dispersive methods (see e.g. Refs. [4, 5]), to analyze the effect of the scalar exchanges in this work. This, of course, would not be possible for processes where the contribution from scalar resonances is dominant, for instance in $\phi \to \eta\pi^0\gamma$ [48, 49], and an improved theoretical treatment would, therefore, be required in those cases.

## B. Beyond the Standard Model: $B$-boson contribution

In analogy to the VMD contributions summarized in the previous subsection, we next define the framework to include intermediate $B$-boson exchanges to the decay amplitude.

---

2 Should $q^2$ be timelike, that is, $q^2 > 0$, then an imaginary part would need to be added to the propagator; this introduces the associated resonance width effects and rids the propagator from its divergent behavior.
The diagrammatic representation of the decay process is depicted in Fig. 1 for the $\eta \to \pi^0\gamma\gamma$ case. This contribution can be assessed from the conventional VMD VVP and $V\gamma$ Lagrangians \[50\]

\[\mathcal{L}_{VVP} = \frac{G}{\sqrt{2}} e^{\mu\nu\alpha\beta} \left[ \partial_\mu V_\nu \partial_\alpha V_\beta P \right], \tag{8}\]

\[\mathcal{L}_{V\gamma} = -4egf_\pi^2\mathcal{A}^\mu \text{tr}[QV_\mu],\]

where $G = 3g^2/4\pi^2 f_\pi$, $\mathcal{A}^\mu$ and $P$ are the matrices for the vector and pseudoscalar meson fields, $A^\mu$ is the photon field, and $Q = \text{diag}\{2/3, -1/3, -1/3\}$ is the quark-charge matrix, supplemented by an effective Lagrangian that describes the $VB$ interaction. The latter is formally identical to the $V\gamma$ Lagrangian with the substitutions $A^\mu \to B^\mu$, $e \to g_B$ and $Q \to \text{diag}\{1/3, 1/3, 1/3\}$, and it is given by

\[\mathcal{L}_{VB} = -\frac{4}{3} g_B g f_\pi^2 B^\mu \text{tr}[V_\mu]. \tag{9}\]

From the $VVP$ and $VB$ Lagrangians in Eqs. (8) and (9), respectively, along with the corresponding $V$-meson propagators, it is straightforward to obtain expressions for the $g_{B\pi\gamma}$ couplings in terms of the generic $B$-boson coupling $g_B$. The $g_{B\pi\gamma}$ couplings are energy dependent and read

\[g_{B\pi\gamma}(q^2) = \frac{eg_p}{4\pi^2 f_\pi} F_\omega(q^2),\]

\[g_{B\eta\gamma}(q^2) = \frac{eg_p}{12\pi^2 f_\pi} \left[c\phi_p F_\omega(q^2) + \sqrt{2}\phi_p F_\phi(q^2)\right], \tag{10}\]

\[g_{B\eta'\gamma}(q^2) = \frac{eg_p}{12\pi^2 f_\pi} \left[s\phi_p F_\omega(q^2) - \sqrt{2}\phi_p F_\phi(q^2)\right],\]

where $\phi_p$ is the $\eta$-$\eta'$ mixing angle in the quark-flavor basis \[51\] and the abbreviations $c\phi_p \equiv \cos \phi_p$ and $s\phi_p \equiv \sin \phi_p$ have been employed. The functions $F_\nu(q^2)$ in the previous equations are form factors that account for the $\omega$ and $\phi$ propagation, and are given by

\[F_\nu(q^2) = \frac{m_\nu^2}{m_\nu^2 - q^2 - im_\nu v}. \tag{11}\]

Combining the $g_{B\pi\gamma}$ and $g_{B\eta\gamma}$ couplings from Eq. (10) with the propagator of the $B$ boson, allows one to find the $B$-boson exchange contribution to the amplitude of the $\eta \to \pi^0\gamma\gamma$ decay analogous to Eq. (5). They are given by

\[\Gamma_{\eta \to B\gamma} = \frac{\alpha_{em} g_B m_\eta^3}{288\pi^3 f_\pi^2} \left(1 - \frac{m_B^2}{m_\eta^2}\right)^3 \times \left[\phi_p F_\omega(m_B^2) + \sqrt{2}\phi_p F_\phi(m_B^2)^2\right]^2, \tag{13}\]

\[\Gamma_{\eta' \to B\gamma} = \frac{\alpha_{em} g_B m_{\eta'}^3}{288\pi^3 f_\pi^2} \left(1 - \frac{m_B^2}{m_{\eta'}^2}\right)^3 \times \left[s\phi_p F_\omega(m_B^2) - \sqrt{2}\phi_p F_\phi(m_B^2)^2\right]^2,\]
for the $B$ production from $\eta^{(l)}$ decays and
\[
\Gamma_{B \rightarrow \pi^0\gamma} = \frac{\alpha_{em}\alpha_{em}m_B^3}{96\pi^4f_\pi^2} \left( 1 - \frac{m_\pi^2}{m_B^2} \right)^3 |F_\omega(m_B^2)|^2,
\]
\[
\Gamma_{B \rightarrow \eta\gamma} = \frac{\alpha_{em}\alpha_{em}m_B^3}{864\pi^4f_\pi^2} \left( 1 - \frac{m_\eta^2}{m_B^2} \right)^3 \times \left[ \phi\phi F_\omega(m_B^2) + \sqrt{2} \phi\phi F_\phi(m_B^2) \right]^2,
\]
\[
\Gamma_{B \rightarrow \eta'\gamma} = \frac{\alpha_{em}\alpha_{em}m_B^3}{864\pi^4f_\pi^2} \left( 1 - \frac{m_\eta'^2}{m_B^2} \right)^3 \times \left[ \phi\phi F_\omega(m_B^2) - \sqrt{2} \phi\phi F_\phi(m_B^2) \right]^2,
\]
for the $B$-boson decays. The leptonic decays arise from the kinetic mixing of the $B$ boson with the photon, cf. Eq. (1), and read [8]
\[
\Gamma_{B \rightarrow e^+\nu} = \frac{\alpha_{em}e^2m_B}{3} \left( 1 + \frac{2m_\tau^2}{m_B^2} \right) \sqrt{1 - \frac{4m_\tau^2}{m_B^2}},
\]
whilst the $B$-boson decay to $\pi^+\pi^-$, which also depends on $\epsilon$, is given by [8]
\[
\Gamma_{B \rightarrow \pi^+\pi^-} = \frac{\alpha_{em}e^2m_B}{12} \left( 1 - \frac{4m_\pi^2}{m_B^2} \right)^{3/2} |F_\pi(m_B^2)|^2,
\]
where $F_\pi(q^2)$ is the pion form factor. Finally, for the three-body decay $\Gamma_{B \rightarrow \pi^+\pi^-\pi^0}$ we make use of the following amplitude
\[
\epsilon_{\beta}^{B\text{boson}} = \frac{g^2GB}{\pi^2f_\pi} \epsilon_{\mu\nu\alpha\beta} \left( \frac{p_\mu^0p_\nu^0}{D_{\rho^0}(s)} + \frac{p_-^\mu p_0^\nu p_0^\alpha}{D_{\rho^-}(t)} + \frac{p_0^\mu p_+^\nu p_+^\alpha}{D_{\rho^+}(u)} \right) \epsilon^B F_\omega(m_B^2),
\]
where $\epsilon_{\beta}$ is the polarization vector of the $B$ boson. $D_{\rho}(q^2)$ is the $\rho$ propagator with energy-dependent width defined in Eq. (4). $p_+, p_-$, and $p_0$ are the four-momenta vectors associated to the $\pi^+$, $\pi^-$, and $\pi^0$, respectively, and the Mandelstam variables $s$, $t$, and $u$ are defined, in this instance, as $s = (p_+ + p_-)^2$, $t = (p_- + p_0)^2$, and $u = (p_+ + p_0)^2$.

### III. LIMITS ON $\alpha_B$ AND $m_B$

In this section, we make use of the theoretical expressions presented in Secs. II A and II B, along with the available experimental data, to place limits on the $B$-boson parameters $\alpha_B$ and $m_B$.

As a preliminary step, we adopt the approach presented in Ref. [8] with the most up-to-date experimental data to generate limits on the $B$-boson parameters from the decays under study, $\eta^{(l)} \rightarrow \pi^0\gamma\gamma$ and $\eta' \rightarrow \eta\gamma\gamma$, which are shown in the form of exclusion plots in Fig. 2. That approach neglects the SM contribution and uses the NWA to place limits upon requiring that the $B$-boson contribution does not exceed the total observed branching ratio (BR) at $2\sigma$. The curves for the $\eta \rightarrow \pi^0\gamma\gamma$ process come from the (preliminary) value found by the KLOE Collaboration, $BR = (1.23 \pm 0.14) \times 10^{-4}$ [36] (black line), and the BR reported by the PDG, $BR = (2.56 \pm 0.22) \times 10^{-4}$ [44] (blue line); we also show the traces obtained from the BESIII Collaboration measurements for the decays $\eta' \rightarrow \pi^0\gamma\gamma$, $BR = (3.20 \pm 0.07 \pm 0.23) \times 10^{-3}$ [52] (red line), and $\eta' \rightarrow \eta\gamma\gamma$, $BR = (8.25 \pm 3.41 \pm 0.72) \times 10^{-5}$ [53] (orange line).

The above limits can clearly be improved by including the contribution from the SM in the theoretical treatment. Taking this into account, the amplitude for these decay processes is written as the coherent sum of the vector, scalar and $B$-boson exchange contributions,
\[
\alpha_B' = \alpha_{\text{VMD}} + \alpha_{\text{SM}} + \alpha_{\text{boson}}
\]
(cf. Secs. II A, II B and Ref. [7]). The corresponding partial decay widths depend on a total of three parameters: i) the baryonic fine-structure constant, $\alpha_B$, ii) the $B$-boson mass, $m_B$, and iii) its total decay width, $\Gamma_B$. However, given that $\Gamma_B$ is not an independent parameter (that is, it can be expressed in terms of $\alpha_B$ and $m_B$), we can reduce the number of free parameters from three to two. Accordingly, the denominator in
Eq. (12), $D_B(q^2)$, is replaced by

$$D_B(q^2) = m_B^2 - q^2 - i \sqrt{q^2} \Gamma_B(q^2), \quad (18)$$

where $\Gamma_B(q^2) = \sum \Gamma_B(q^2)$ is the energy-dependent width of the $B$ boson, with the sum running over the partial widths of the various decay channels the $B$ boson can decay into.

$$\Gamma_B(q^2) = \theta(q^2 - m_B^2) \frac{\gamma_{B \rightarrow \pi^0 \gamma}(q^2)}{\gamma_{B \rightarrow \pi^0 \gamma}(m_B^2)} \Gamma_{B \rightarrow \pi^0 \gamma} + \theta(q^2 - 4m_\pi^2) \frac{\gamma_{B \rightarrow e^+e^-}(q^2)}{\gamma_{B \rightarrow e^+e^-}(m_B^2)} \Gamma_{B \rightarrow e^+e^-} + \theta(q^2 - 4m_\mu^2) \frac{\gamma_{B \rightarrow \mu^+\mu^-}(q^2)}{\gamma_{B \rightarrow \mu^+\mu^-}(m_B^2)} \Gamma_{B \rightarrow \mu^+\mu^-}$$

$$+ \theta(q^2 - 4m_\pi^2) \frac{\gamma_{B \rightarrow \pi^+\pi^-}(q^2)}{\gamma_{B \rightarrow \pi^+\pi^-}(m_B^2)} \Gamma_{B \rightarrow \pi^+\pi^-} + \theta(q^2 - 9m_\pi^2) \frac{\gamma_{B \rightarrow \pi^0\pi^0}(q^2)}{\gamma_{B \rightarrow \pi^0\pi^0}(m_B^2)} \Gamma_{B \rightarrow \pi^0\pi^0}, \quad (19)$$

For our study, we include the partial widths of the decay channels $B \rightarrow \pi^0 \gamma$, $e^+e^-$, $\mu^+\mu^-$, and $\pi^+\pi^-$ given, respectively, in Eqs. (14)–(16), whilst for the partial width of the $B \rightarrow \pi^0 \pi^0$, we make use of the amplitude in Eq. (17) to obtain numerical results after squaring and numerically integrating over its corresponding phase space. The energy-dependent width $\Gamma_B(q^2)$ can, therefore, be written as

$$\Gamma_B(m_B^2)/\alpha_B, \quad \text{as a function of} \ m_B$$

where the $\gamma_i(q^2)$ parameters are given by the following expressions

$$\gamma_{B \rightarrow \pi^0 \gamma}(q^2) = (q^2)^{3/2} \left(1 - \frac{m_\pi^2}{q^2}\right)^3 |F_\omega(q^2)|^2,$$

$$\gamma_{B \rightarrow e^+e^-}(q^2) = \sqrt{q^2} \left(1 + \frac{2m_\pi^2}{q^2}\right) \sqrt{1 - \frac{4m_\pi^2}{q^2}}, \quad (20)$$

$$\gamma_{B \rightarrow \pi^+\pi^-}(q^2) = \sqrt{q^2} \left(1 - \frac{4m_\pi^2}{q^2}\right)^{3/2} |F_\pi(q^2)|^2,$$

whilst $\gamma_{B \rightarrow \pi^0\pi^0}(q^2)$ must be evaluated numerically. In Fig. 3, the total normalized width $\Gamma_B(m_B^2)/\alpha_B$ is plotted as a function of $m_B$.

Next, we proceed to calculate the constraints on the $B$-boson parameters $\alpha_B$ and $m_B$ set by experiment. We start with the $\eta \rightarrow \pi^0\gamma\gamma$ decay using the PDG reported value, $BR = (2.56 \pm 0.22) \times 10^{-4}$ [44], as well as the (preliminary) value from the KLOE Collaboration, $BR = (1.23 \pm 0.14) \times 10^{-4}$ [36] (see also Ref. [54]). In Fig. 4, we show the limits in the $\alpha_B$-$m_B$ plane, which are found by requiring our predictions to not exceed the corresponding branching ratios at 2$\sigma$. The gray area is excluded by the data from KLOE, which yield a more stringent limit than the resulting one from the PDG (solid red line). This is as expected given that the BR from KLOE is found to be in good agreement with our SM prediction from Ref. [7], $BR = (1.35 \pm 0.08) \times 10^{-4}$, and, thus, the KLOE constraints on the $B$ boson turn out to be stronger. The dashed black line in the figure is found using the data from KLOE but with the SM (or, equivalently, QCD) contributions set to zero. Clearly, these contributions are not negligible as the limits on $\alpha_B$ become an order of magnitude weaker when their effects are turned off (labeled QCD off in the plots). The uncertainty in the exclusion limits associated to the systematic errors of our theoretical treatment is presented in Appendix A.

The shape and size of the excluded region in Fig. 4 contains key physical information. In this figure, three different regions are observed. The first one corresponds to $m_B \lesssim m_{\pi^0}$, where $\alpha_B \sim 0(1)$. At $m_B \sim m_{\pi^0}$, the limit placed on the coupling plummets by almost six orders of magnitude down to $\alpha_B \sim 10^{-6}$; it then moderately increases, to finally take a steep rise when $m_B$ approaches $m_{\eta}$, reaching $\alpha_B \sim 10^{-2}$. Finally, for $m_B \gtrsim m_{\eta}$ the constraint on the coupling grows very smoothly as $m_B$ increases. Out of the three, the $m_{\pi^0} \lesssim m_B \lesssim m_{\eta}$ region deserves special attention and raises the question as to why $\alpha_B$ is constrained so strongly there. The answer to this is related to the fact that the $B$-boson width is extremely small in this region of parameter space.

Let us look into this in more detail. By noticing from Fig. 3 that within the $m_{\pi^0} \lesssim m_B \lesssim m_{\eta}$ mass range the NWA is valid, it allows us to write the squared modulus of the $B$-boson propagator as $\pi/(m_B \Gamma_B(t - m_B^2))$, under the phase-space integral. For a $B$ boson whose squared mass falls within the kinematic space for the $t$ variable, i.e. $t_{\min} \leq m_B^2 \leq t_{\max}$, the phase-space integral over $dt$ places the $B$ boson on shell and one is allowed to write

$$\Gamma(\eta \rightarrow \pi^0\gamma\gamma) \propto \int \frac{\alpha_B^2 dt}{D_B(t)^2} \to \frac{\alpha_B^2 \pi}{m_B \Gamma_B(m_B^2)}. \quad (21)$$

As it can be seen in Fig. 3, $\Gamma_B(m_B^2)/\alpha_B$ is very small within the kinematic region of interest for the present discussion.
(i.e. $m_{\rho} \lesssim m_B \lesssim m_\eta$), which, in the $\Gamma_B(t)/\alpha_B \to 0$ limit, forces $\alpha_B \to 0$ so that $\Gamma(\eta \to \pi^0\gamma\gamma)$ remains finite.

Next, we show the exclusion plots associated to the two $\eta^\prime$ decays in Fig. 5. On the left-hand side, we display the region of the $\alpha_B$-$m_B$ plane excluded by the BESIII Collaboration $\eta^\prime \to \pi^0\gamma\gamma$ measurement, $BR = (3.20 \pm 0.07 \pm 0.23) \times 10^{-3}$ [52], and, on the right-hand side, the corresponding one for the $\eta^\prime \to \eta\gamma\gamma$, $BR = (8.25 \pm 3.41 \pm 0.72) \times 10^{-5}$ [53], both at a confidence level of 2σ.

The shape of the excluded region for the $\eta^\prime \to \pi^0\gamma\gamma$ is clearly different to that of the $\eta \to \pi^0\gamma\gamma$ decay (cf. Fig. 4). In particular, the limits within the $m_{\rho} \lesssim m_B \lesssim m_\eta$ mass range, whilst still showing the shape resembling a keel, are about four orders of magnitude weaker than those coming from $\eta \to \pi^0\gamma\gamma$. There are two contributing effects required to explain this. On the one hand, there are inherent dynamical differences in the $B$-boson production of the two decays [cf. Eq. (13)]. On the other hand, there are kinematic influences that also need to be accounted for. Specifically, if one applies the NWA to both the $B$ boson and $\omega$ propagators, a factor like $\delta(t - m_\rho^2)\delta(t - m_\omega^2)$ is obtained, which under the phase-space integral results in $\delta(m_\rho^2 - m_\omega^2)$.

This Dirac delta suppresses the contribution of the $B$ boson to the decay process when $m_B \neq m_\omega$ and, hence, forces the exclusion limit to be weaker in this region. In contrast, the $B$-boson contribution is largely amplified when $m_B \approx m_\omega$ and, therefore, the exclusion limit becomes much stronger in this area, which will make it difficult to experimentally identify a $B$ boson with a mass around the pole of the $\omega$ resonance. The region $m_\eta \lesssim m_B \lesssim m_\omega$ is less constrained, and, thus, appears to be a good place to look for an enhancement in the $\pi^0\gamma$ invariant mass spectrum.

The limits from the $\eta^\prime \to \eta\gamma\gamma$ process (right plot in Fig. 5) in the $m_\eta \gtrsim m_B \lesssim m_\eta$ region are similar to the ones from $\eta^\prime \to \pi^0\gamma\gamma$. Having said that, the keel shape appearing in the $m_{\rho} \lesssim m_B \lesssim m_\eta$ mass range of the $\eta \to \pi^0\gamma\gamma$ and $\eta^\prime \to \pi^0\gamma\gamma$ exclusion plots is missing in the $\eta^\prime \to \eta\gamma\gamma$ one, which is down to the fact that the phase space of the latter does not allow the $B$ boson to resonate in this range of $B$-boson masses and, therefore, the constraints turn out to be weaker.

All in all, the $\eta^\prime \to \pi^0\gamma\gamma$ and $\eta^\prime \to \eta\gamma\gamma$ decays do not appear to be as powerful as the $\eta \to \pi^0\gamma\gamma$ for constraining the $B$-boson parameters.

The smoking gun signature of a $B$ boson in the $m_{\rho} \lesssim m_B \lesssim m_\eta$ region would be the observation of a peak at around $m_B$ in the $\pi^0\gamma$ invariant mass distribution. In Fig. 6, we show the quantitative effect of a $B$ boson on the $\eta \to \pi^0\gamma\gamma$ decay using two sets of representative values for $\alpha_B$ and $m_B$ from the not-excluded region of parameter space

$$\alpha_B = 10^{-6}, \quad m_B = 250\text{ MeV}, \quad (22)$$

and

$$\alpha_B = 10^{-2}, \quad m_B = 540\text{ MeV}. \quad (23)$$

In this figure, the solid black line corresponds to our SM prediction from Ref. [7], whereas the effect of including the $B$ boson is shown by the dashed red and dotted green lines for the two sets of $\alpha_B$ and $m_B$ values from Eqs. (22) and (23), respectively. As it can be seen, the differences in the distribution introduced by the $B$-boson contribution are very small and it is very difficult to distinguish the associated lines from the SM prediction. That is, the allowed values for $\alpha_B$ in the $m_{\rho} \lesssim m_B \lesssim m_\eta$ region are so small that it makes the $B$-boson signal strongly suppressed, rendering the task of experimentally identifying it nearly impossible. For this reason, a $B$ boson in the mass range $m_{\rho} \lesssim m_B \lesssim m_\eta$ cannot explain the normalization offset that appears to be affecting the experimental $\gamma\gamma$ invariant mass distribution from the A2 [55] and Crystal Ball [56] Collaborations with respect to our VMD and $\Lambda\sigma\pi$ prediction [7].

Let us now move on to perform statistical fits to the available experimental diphoton spectra to determine the region of the $\alpha_B$-$m_B$ plane (cf. Fig. 4) that is preferred by the data. From the Crystal Ball $\gamma\gamma$ invariant mass spectrum [56], we obtain the following best fit values

$$\alpha_B = 0.40^{+0.07}_{-0.08}, \quad m_B = 583^{+32}_{-20}\text{ MeV}, \quad (24)$$

with a $\chi^2_{\text{min}}$/d.o.f. = 0.42/5 = 0.08, whereas, for the KLOE (preliminary) data [54]6, we find

$$\alpha_B = 0.049^{+0.07}_{-0.06}, \quad m_B = 135^{+11}_{-13}\text{ MeV}. \quad (25)$$

6 Whilst KLOE has published a BR for the $\eta \to \pi^0\gamma\gamma$ process in a conference proceedings [36], the diphoton spectrum has not yet been published, although it was presented at The 10th International Workshop on Chiral Dynamics 2021 [54]. For our analysis, we have retrieved the data points from their presentation’s figure. We thank KLOE for the email communications [57].
mated by perturbing one of the parameters at a time such that its χ² errors associated to the experimental points from Crystal Ball, the black line) with an estimation of the uncertainty from the estimated parameters from Eq. (24) are ruled out by the KLOE data (cf. Fig. 4), whose measured BR continues the decreasing trend seen over the decades associated to more precise measurements becoming available (see Ref. [6]). In turn, this trend supports the theoretical treatment without a precise measurements coming available (see Ref. [6]). In turn, this trend supports the theoretical treatment without a B boson in the π and ρ channels, with parameters from Eq. (24), helps explain the tension between the Crystal Ball spectrum and the SM result [7]. Notwithstanding this, the best fit parameters from Crystal Ball in Eq. (24) are ruled out by the KLOE data (cf. Fig. 4), whose measured BR continues the decreasing trend seen over the decades associated to more precise measurements becoming available (see Ref. [6]). In turn, this trend supports the theoretical treatment without a B boson, as our VMD and LσM approach from Ref. [7] appears to be capable of successfully predicting the experimental data for the three η → π⁺γγ and η′ → π⁺γγ decays simultaneously. Clearly, the experimental situation is far from conclusive and it may not be possible to make categorical statements about the need for a B boson until the arrival of new and more precise data, e.g. from the KLOE-(II) and JEF [37] experiments.

Next, we perform fits to the η → π⁺γγ diphoton spectrum from the BESIII Collaboration [52], which may be used to explore larger B-boson masses. No distribution data is available for the η → ηγγ process, so the constraints from this channel come from the branching ratio only (see Fig. 5). The fit to the η → π⁺γγ data yields

\[ \alpha_B = 0.005(1), \quad m_B = 759(1) \text{ MeV}, \]

with χ² min /d.o.f = 11.73/11 = 1.07. The distribution using the fitted parameters from Eq. (26) is shown in Fig. 8 (dotted red line), together with the experimental data (blue squares) and the SM prediction [7] (solid black line) with an estimation of its uncertainty. It is worth noticing the sudden drop in the dotted red line (i.e. SM with B-boson distribution) at m_B^2 ≈ 0.33 GeV². What is interesting about this is that, even

with a χ² min /d.o.f = 4.46/5 = 0.89. Because of the large errors associated to the experimental points from Crystal Ball, its χ² min /d.o.f turns out to be extremely small. The χ² min /d.o.f of the fit to the KLOE data implies a good quality of the fit. The errors associated to the fitted parameters have been estimated by perturbing one of the parameters at a time such that χ² = χ² min + 1 [44]. The theoretical γγ invariant mass spectra using the parameters from the fits in Eqs. (24) and (25) to the Crystal Ball and KLOE data are shown in Fig. 7 with dashed and dotted black lines, respectively. Also plotted are the experimental data points and the SM prediction [7] (solid black line) with an estimation of the uncertainty from the error propagation of the Vπγγ couplings. The different individual contributions to the invariant mass spectra are shown in Appendix B 1. It is worth noticing that the inclusion of a nonresonant B boson in the t and u channels, with parameters from Eq. (24), helps explain the tension between the Crystal Ball spectrum and the SM result [7]. Notwithstanding this, the best fit parameters from Crystal Ball in Eq. (24) are ruled out by the KLOE data (cf. Fig. 4), whose measured BR continues the decreasing trend seen over the decades associated to more precise measurements becoming available (see Ref. [6]). In turn, this trend supports the theoretical treatment without a B boson, as our VMD and LσM approach from Ref. [7] appears to be capable of successfully predicting the experimental data for the three η → π⁺γγ and η′ → π⁺γγ decays simultaneously. Clearly, the experimental situation is far from conclusive and it may not be possible to make categorical statements about the need for a B boson until the arrival of new and more precise data, e.g. from the KLOE-(II) and JEF [37] experiments.

Next, we perform fits to the η′ → π⁺γγ diphoton spectrum from the BESIII Collaboration [52], which may be used to explore larger B-boson masses. No distribution data is available for the η′ → ηγγ process, so the constraints from this channel come from the branching ratio only (see Fig. 5). The fit to the η′ → π⁺γγ data yields

\[ \alpha_B = 0.005(1), \quad m_B = 759(1) \text{ MeV}, \]

with χ² min /d.o.f = 11.73/11 = 1.07. The distribution using the fitted parameters from Eq. (26) is shown in Fig. 8 (dotted red line), together with the experimental data (blue squares) and the SM prediction [7] (solid black line) with an estimation of its uncertainty. It is worth noticing the sudden drop in the dotted red line (i.e. SM with B-boson distribution) at m_B^2 ≈ 0.33 GeV². What is interesting about this is that, even

7 We also carried out fits to the A2 data but did not find convergent solutions using two free parameters. When fits were attempted using the B-boson width as an additional free parameter, though, good convergence was achieved.

8 This sudden drop can be understood as follows: so long as t_{min}(s) ≤ m_B^2 ≤
though the $\chi^2_{\text{min}}/\text{d.o.f}$ of this fit is very good, the associated integrated branching ratio deviate from the experimental counterpart due to the effect of the wiggle on the distribution. Also, the spectrum using the fit parameters would lead to larger than observed bin values for the experimental points 10 and 11. Again, the different individual contributions to the $\gamma\gamma$ invariant mass spectrum are presented in Appendix B 2.

Finally, a joint fit to the experimental invariant mass spectra from KLOE and BESIII for the $\eta \to \pi^0\gamma\gamma$ and $\eta' \to \pi^0\gamma\gamma$ decays, respectively, is carried out. The joint fit yields

$$\alpha_B = 0.005(1), \quad m_B = 759(1) \text{ MeV}, \quad (27)$$

with $\chi^2_{\text{min}}/\text{d.o.f} = 19.61/18 = 1.09$. The joint fit produces the same best fit parameters as those from the fit to the $\eta' \to \pi^0\gamma\gamma$ spectrum only. The theoretical distribution for the $\eta \to \pi^0\gamma\gamma$ decay using the parameters from the joint fit is shown in Fig. 9 (dotted red line), which turns out to be indistinguishable from that of the SM (solid black line).

To conclude, it is worth highlighting that both our SM and SM with $B$-boson predictions (using the joint fit parameters for the latter) agree well with both sets of experimental data points. The largest differences between the theoretical predictions still show compatibility at roughly the 1σ level. We, therefore, conclude that the experimental data from KLOE and BESIII for the $\eta \to \pi^0\gamma\gamma$ and $\eta' \to \pi^0\gamma\gamma$ decays, respectively, do not require a $B$-boson contribution, in spite of the coupling $\alpha_B$ being clearly nonzero.

This conclusion differs from that of the study in Ref. [58], where it is argued that the simultaneous prediction of the three processes under study may require the presence of a leptoophobic $B$ boson, which, in turn, was motivated by some of the

---

$\chi^2_{\text{min}}(s) \forall s \in [s_{\text{min}}, s_{\text{max}}]$, then the available phase space allows the $B$ boson to resonate; however, for values of $s$ such that $t_{\text{min}}(s) \geq m_B^2$ or $t_{\text{max}}(s) \leq m_B^2$, then the $B$ boson no longer resonates and its contribution to the amplitude suddenly plummets producing the sudden drop in the distribution. It must be noted that this effect also applies to the $\omega$ meson and is responsible for the sudden drop in the SM distribution around $m_{\gamma\gamma}^2 \approx 0.30 \text{ GeV}^2$. Given that this is a kinematic effect, it will always be present in the spectrum so long as $t_{\text{min}}(s_{\text{min}}) \leq m_B^2 \leq t_{\text{max}}(s_{\text{min}})$, although it becomes a relatively small effect and is difficult to detect beyond $m_{\gamma\gamma}^2 \gtrsim 0.4 \text{ GeV}^2$ for this particular decay.

---

$^9$ There is a secondary local minimum giving $\alpha_B = 5(2) \times 10^{-4}$ and $m_B = 780^{+6}_{-4} \text{ MeV}$, with $\chi^2_{\text{min}}/\text{d.o.f} = 23.71/18 = 1.32$. These values for the $\alpha_B$ and $m_B$ parameters yield a $B$-boson width of $\Gamma_B \approx 5.1 \text{ MeV}$. For this particular solution, both $m_B$ and $\Gamma_B$ are effectively the same as those of the $\omega$ vector meson. Accordingly, the end effect is to enhance the spectrum with respect to the SM prediction for $m_{\gamma\gamma}^2 \lesssim 0.30 \text{ GeV}^2$, where the available phase space allows both the $\omega$ and $B$ boson to resonate, and has no effect on the spectrum beyond this point, i.e. $m_{\gamma\gamma}^2 \gtrsim 0.30 \text{ GeV}^2$. 

FIG. 7. KLOE (green triangles) [54], A2 (blue circles) [55] and Crystal Ball (red squares) [56] measurements of the $m_{\gamma\gamma}^2$ spectrum for the $\eta \to \pi^0\gamma\gamma$ decay, as well as the SM (VMD and LoM) prediction [7] (solid black line) and SM with $B$-boson predictions using the fitted parameters from Eqs. (24) and (25).}

FIG. 8. BESIII (blue squares) [52] measurements of the $m_{\gamma\gamma}^2$ spectrum for the $\eta' \to \pi^0\gamma\gamma$ decay, as well as the SM (VMD and LoM) prediction [7] (solid black line) and SM with $B$-boson prediction using the fitted parameters from Eq. (26) (dotted red line).

FIG. 9. KLOE measurements (green triangles) [54] of the $m_{\gamma\gamma}^2$ spectrum for the $\eta \to \pi^0\gamma\gamma$ decay together with the SM (VMD and LoM) prediction [7] (solid black line) and SM with $B$-boson prediction using the fitted parameters from Eq. (27) (dotted red line).
FIG. 10. Limits on the leptophobic $B$-boson mass $m_B$ and coupling $\alpha_B$ from the BR measurements of the decays $\eta \to \pi^0\gamma\gamma$ (gray) by KLOE [36], and $\eta' \to \pi^0\gamma\gamma$ (red) [52] and $\eta' \to \eta\gamma\gamma$ (blue) [53] by BESIII.

collections from our previous work in Ref. [7]. It should be noted, though, that in Ref. [58] the $B$-boson mass and width were manually fixed to some values that the author deemed reasonable, leaving the $g_{B\eta\gamma}$ couplings as free constant parameters that were subsequently fitted to the experimental data. Contrary to this, in the present work $\Gamma_B$ is not an independent variable but a function of both $\alpha_B$ and $m_B$ (under the assumption that the $B$ boson decays to SM particles only), which are then left as free parameters in our fits. It is worth noting that in our analysis the $g_{B\eta\gamma}$ couplings are not constant but energy dependent. More importantly, Ref. [58] did not employ the most recent experimental data for the $\eta \to \pi^0\gamma\gamma$ decay from the KLOE Collaboration [54] in his analysis.

IV. CONCLUSIONS

We have analyzed in detail the sensitivity of the rare decays $\eta^{(\prime)} \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ to a leptophobic $U(1)_B$ boson in the MeV–GeV mass range. Adding the explicit $B$-boson exchange contribution in the $t$ and $u$ channels, in addition to our SM (VMD and LoM) amplitudes, has allowed us to place stringent limits on the $B$-boson parameters $m_B$ and $\alpha_B$ by comparing with current experimental data. A visual summary of these limits is shown in Fig. 10. From the individual analysis of the $\eta \to \pi^0\gamma\gamma$ decay, we have strengthened by one order of magnitude the current constraints in the resonant mass region $m_{\pi^0} \lesssim m_B \lesssim m_\eta$, reaching $\alpha_B \sim 10^{-6}$, as it can be seen in the figure. These constraints would make a $B$-boson signature strongly suppressed, rendering the task of experimentally identifying it as a peak around $m_B$ in the $\pi^0\gamma$ invariant mass distribution practically impossible.

Our analysis of the most recent experimental $\gamma\gamma$ invariant mass distribution from the KLOE Collaboration supports the description of the processes studied in this work without contribution from a potential new leptophobic $B$ boson, as our VMD and LoM treatment is capable of simultaneously predicting the three $\eta^{(\prime)} \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ decays with remarkable agreement with the experimental data. However, a $B$ boson with a mass $m_B \gtrsim m_\eta$ and non-negligible coupling $\alpha_B$ may help explain the discrepancy between our SM prediction and the experimental data from the A2 and Crystal Ball Collaborations (see Fig. 7). The existing tension between the measurements by different experimental groups does not allow us to make an absolute statement about the need for a $B$ boson, as the branching ratio observed by KLOE, whilst in agreement with our SM prediction, is about a factor of two smaller than those from A2 and Crystal Ball. This highlights the need for new and more precise data, e.g. from the KLOE(-II) and JEF experiments.

Finally, the $\eta' \to \pi^0\gamma\gamma$ and $\eta' \to \eta\gamma\gamma$ decays are not as powerful as the $\eta \to \pi^0\gamma\gamma$ at constraining $B$-boson parameters below $m_\eta$ but allow exploring larger $B$-boson masses. As it can be observed in Fig. 10, the region in the $m_B$-$\alpha_B$ plane shows a sharp dip, which would make the task of identifying a $B$ boson with $m_B \sim m_\eta$ very challenging. However, the mass region $m_\eta \lesssim m_B \lesssim m_\omega$ is less constrained, and, thus, appears to be a good place to look for an enhancement in the $\pi^0(\eta)\gamma$ invariant mass distributions, for example, at BESIII or the JEF experiment.

Appendix A: Model uncertainty analysis

In this appendix, we provide an estimation of the uncertainty related to the models employed in our theoretical treatment. In particular, and based on the arguments laid out in the last two paragraphs of Sec. II A, one can assess this uncertainty by just propagating the errors associated to the couplings in Table I to the final results. In Fig. 11, we show the limits on the leptophobic $B$-boson coupling $\alpha_B$ for different $m_B$ masses from the $\eta \to B^0\gamma\gamma$ BR measurement by KLOE (black line) along with an error band due to the uncertainties of the $VP\gamma$ couplings (gray band). Despite the error band being rather large, the corresponding limits are clearly different from those with the QCD contributions turned off (dashed line).
V P (black line) along with an error band due to the uncertainties of the contributions to the spectra (solid black), together with the separate VMD (dashed black), LσM experimental datasets, respectively. The results shown in Eqs. (25) and (24) obtained from the KLOE first and second columns in this figure correspond to the fit result in Eq. (26) are also presented. The entire contribution of the $B$ boson, which accounts for 8%, the interference between vector and scalar exchanges, accounting for 4%, and the interference between scalar and $B$-boson exchanges, which is constructive and around 1%. The contribution of scalar meson exchanges is very small.

2. $\eta' \to \pi^0 \gamma \gamma$ decay

In Fig. 13, the different individual contributions to the $\gamma \gamma$ invariant mass distribution for the $\eta' \to \pi^0 \gamma \gamma$ decay using the fit result in Eq. (26) are also presented. The entire contribution to the spectrum (solid black), together with the separate VMD (dashed black), LσM (dotted black) and $B$ boson (dot-dashed black) contributions, as well as their interferences, are displayed.

As observed, the exchange of vector mesons dominate the KLOE spectra, contributing 114% to the entire signal. The contribution of scalar exchanges accounts for less than 1%, whilst the contribution from the $B$ boson is only 1.9%, making their separate effects very challenging to isolate, even with the arrival of new and more precise data. The interference between vector and scalar exchanges is constructive and accounts for about 8%, whereas the interference between vector and $B$-boson exchanges is destructive, $-23\%$, with a visible effect in the distributions at low $\gamma \gamma$ and $\pi^0 \gamma$ invariant masses. The interference between scalar and $B$-boson exchanges is tiny, with less than $-1\%$, and constructive.

The contributions to the Crystal Ball spectra show a rather different behavior. Again, the contribution of vector meson exchanges prevails, but in this case it accounts only for 49% of the entire signal. The interference between vector and $B$-boson exchanges is constructive and almost as large as the VMD signal, contributing with 38%. The remaining 13% comes from the individual effect of the $B$ boson, which accounts for 8%, the interference between vector and scalar exchanges, accounting for 4%, and the interference between scalar and $B$-boson exchanges, which is constructive and around 1%. The contribution of scalar meson exchanges is insignificant.

Appendix B: Individual contributions to the invariant mass distributions

1. $\eta \to \pi^0 \gamma \gamma$ decay

For completeness, in Fig. 12, the different individual contributions to the $\gamma \gamma$ (first row) and $\pi^0 \gamma$ (second row) invariant mass distributions for the $\eta \to \pi^0 \gamma \gamma$ decay are presented. The first and second columns in this figure correspond to the fit results shown in Eqs. (25) and (24) obtained from the KLOE and Crystal Ball experimental datasets, respectively. The entire contribution to the spectra (solid black), together with the separate VMD (dashed black), LσM (dotted black) and $B$-boson (dot-dashed black) contributions, as well as their interferences, are displayed.
