Abstract— Heavy metal contamination is an important environmental problem all over the world. High concentrations of heavy metals cause permanent damage to cells and tissues. In this study, the toxic effects of zinc heavy metal in sunflower plant in population and molecular parameters were investigated. The effects of zinc heavy metal in sunflower seedlings were determined using the changes in population parameters: root length, dry weight, and total soluble protein content. Total protein content of sunflower plants was determined in a relationship in the opposite direction increasing the amount of metal concentrations. Genotoxic effects of heavy metal of zinc on sunflower plants were revealed by using changes in genomic template stability (GTS). According to analyses, serious changes in genomic template stability were detected and these results were compared with the growth, dry weight and total soluble protein content of the seedlings grown at various zinc concentrations. Also, it was seen that the genomic template stability significantly affected the primary root length, root dry weight and root total soluble protein content. Positive correlations were observed between physiological, biochemical and molecular parameters in sunflower seedlings under zinc stress. In conclusion, a comparison between physiological, biochemical and molecular parameters shows that zinc is a genotoxic agent for sunflower plants.

Keywords— Genotoxic effect; Heavy metal; Sunflower; Zinc stress.

I. INTRODUCTION

Sunflower (Helianthus annuus L.) has economic importance in terms of agriculture in the worldwide. The high level of its fatty acid (69%) easily explains the importance of the sunflower plant (Lentz et al., 2008; Blackman, 2011). Environmental pollution took place because of the necessity to create areas for urbanized living and then it has increased since then with the improvement of industry. Especially after 1950s, the rapid growth of the population has caused our natural resources to be polluted even more and the ecosystem has got serious damages (Yarsan et al., 2000). If the environmental changes affect a plant’s normal growth and development in a negative way, the reaction or the general situation of the plant is called stress. According to Levitt, stress factors have two different groups; biotic and abiotic. According to this classification, abiotic factors are the most dangerous ones which include heavy metals and threaten the ecological balance (Levitt, 1972). Heavy metals which can be heavily accumulated in soil, water and air is now a common environmental concern to take precautions immediately and it is equally dangerous for every living organism from plants to human (Yarsan et al., 2000). Several industrial activities, urban waste, exhaust gases, mining activities, some volcanic activities, disinfection and fertilisation held in agriculture, heavy use of pesticides are some of the examples of heavy metal pollution. This pollution also causes decrease in the quality of agricultural products (KirbagandMunuzorglu, 2006). Heavy metals also give damage to most of the functional biomolecules including membrane lipids and this results in increase of some reactive oxygen types such as (ROS), hydroxyl radicals, (OH⁻) or hydrogen peroxide, (H₂O₂) superoxide anion, (O₂⁻) which cause oxidative stress (BurzynskiandKlobus, 2004;Koc et al., 2012). It is also known that heavy metals cause genotoxicity in living things. This situation occurs as a results of treating organisms with some chemical, biological and physical agents that leads to damages in their genetic materials (Steinkellner et al., 1998;Savva, 2000;Hall, 2002). Zinc is a microelement which should be taken in very less amounts by plants, animals and humans. In the deficiency of zinc, RNA levels and the cell’s ribosome content decrease and this situation leads to a decrease in the protein formation mechanism. Besides, in deficiency of zinc in the plants, indexes of indol-3-acetic acid (IAA), abscisic acid and tryptophan amino acid levels also decreases. This situation gives damages to the normal growth of the plants and affects the herbal production in a serious way. The toxic effect of Zn²⁺ cause damages to the
cell division and it especially gives damages to the cell nucleus of meristematic stem cell (Koc et al., 2012). At the same time, Zn²⁺ stress results in chlorosis, which is defined as a damage in the activity of chloroplast and shrinking of the plant’s size. It also affects the productivity and decreases the amount of chlorophyll and resolvable proteins, the length of the root, the weight and the amount of the seed (Khurana and Chatterjee 2001; Bekiaroglu and Karataglis, 2002; Koc et al., 2012). In this current study, it was aimed to determine the effect of zinc heavy metal on sunflower seedlings by the use of physiological parameters such as stem/root elongation and RAPD analysis for possible genotoxicity, which is one of the PCR-based molecular indicators.

II. MATERIAL AND METHODS

Germination method, measurement of total soluble protein and length of root

Sunflower seeds’ surfaces were sterilized with 70% alcohol and 30% sodium hypochlorite solution and washed three-four times with distilled water. For germinating and growing of sunflower seeds, seedling trays were filled with sterilized perlite and seeds were planted in each cell of seedling tray. The seedling trays were divided into eight groups in total, including control and seven different concentrations of zinc solution. Control group of the tray was treated with only 15 mL of distilled water. The other groups of the trays were treated with 15 mL of 20, 40, 80, 160, 320, 640 and 1280 mg L⁻¹ concentrations of ZnSO₄·6H₂O zinc solutions for each, respectively. These treatments were replicated twice. All these procedures were performed for 21 days. After 21 days of treatment, each plant samples’ root and stem length belonging to different groups of sunflower seedlings were measured and the harvested plants were frozen in liquid nitrogen and stored at -20°C until DNA extraction. Total soluble protein of the sunflower seedlings were measured according to the Bradford method (Bradford, 1976).

DNA extraction and RAPD procedures

The piece (200mg) of roots obtained from the seedlings after 21 days of growth procedure was grounded with liquid nitrogen in eppendorf tubes, and total genomic DNA isolation was performed with the DNA isolation protocol of Lefort (Lefort, 1998). The quantity and quality of DNA samples were determined by Nanodrop Spectrophotometer (ND-1000, Thermo Scientific) and also confirmed by gel electrophoresis which contains 1.5% agarose and 0.05μl mL⁻¹ ethidium bromide. After then, the DNA samples with suitable purity and concentration levels were selected to be used in RAPD procedure. RAPD-PCR study was performed with total 25μl of standard reaction volume for each sample. Optimum amplification conditions were obtained with 200ng genomic DNA, 1× reaction buffer, 2.5mM MgCl₂, 20μM dNTPs, 0.2mM primer, and 0.5U Taq DNA polymerase (Promega). 14 of 20 RAPD primers used in this study revealed polymorphic bands that are different from the control group of sunflower. Fourteen RAPD primers [5¹—³; (OPA-03) AGTCAGCCAC; (OPA-08) GTGACGTTAGG; (OPB-07) GGTGAGCAGCAG; (OPC-01) TTCGAGCCAG; (OPC-02) GTGAGGGCTG; (OPC-04) CCGCATCTAC; (OPC-05) TGGACCGGTG; (OPC-06) GAACGACTC; (OPC-07) GTGCCCGAGCA; (OPC-08) TGACGGGTG; (OPC-09) CTCACCGTCC; (OPC-10) TGTCCTGGGTG; (OPC-11) AAAGCTGCGG; (OPF-05) CCGAACGATCC] were used for RAPD-PCR reactions. The thermal cycling conditions included an initial denaturation step at 95°C for 5 min, followed by 35 cycles of 94°C for 90s (denaturation), 36°C for 60s (annealing), and 72°C for 120s (extension) followed by a final extension period of 72°C for 5 min. Negative control PCR, not including any DNA template was run for each samples for testing any other kinds of DNA contaminations. All PCR reactions were carried out in duplicate. PCR reaction products and DNA ladder (DNA ladder plus, Promega 100bp) were subjected to an electrophoretic separation process for 2-2.5h, under 5V cm⁻¹ current in 1.5% agarose gel containing 0.05μl mL⁻¹ ethidium bromide. The gels were displayed with UV imaging system and photographed with using GyneSnap Software (Synoptics Co). After then, the gel photographs were analyzed for identifying the RAPD profiles.

Calculating the genomic template stability (GTS)

After analysis of the RAPD profiles, genomic template stability (%) was calculated with the following formula:

\[ \text{GTS} = \frac{1 - a_n}{1} \times 100 \]

where letter of a refers to polymorphic band number of each sample, which was treated with the different zinc solutions and the letter of n refers to the total band number in the control. The appearance or disappearance of bands in the treated samples’ RAPD profiles in comparison to the control profiles were identified as polymorphism.

Statistical analysis

The SPSS (statistical package software v. 17.0 Multi-language for Windows) was used to analyze the changes in root length, dry weight and total soluble protein content. Data were tested by performing the paired sample t-test.

III. RESULTS AND DISCUSSION

The effect of zinc on physiological and biochemical parameters

One of the effects of toxins is to prevent the root and body growth. The accumulation of heavy metals in plant causes
negative effects on roots, stems and germination of seeds; when it is exposed to the increasing concentrations of heavy metals (Zengin and Munzuroglu, 2004). Similarly, as expected in sunflower plants, the findings of this study on the length of sunflower seedlings' roots and stems are similar with the related literature. In this study, for 21 days, when the samples which were exposed to heavy metal stress with different Zn$^{2+}$ concentrations are evaluated, the improvement of plants' roots and stems length have suggested that there is a clear decrease in parallel with the increasing concentration of Zn$^{2+}$, as expected. However, it was observed that there was an increase in root and stem lengths and improvement of plants which were exposed to 20mg L$^{-1}$ and 40mg L$^{-1}$ of zinc stress. It was found that, in the plant samples which were exposed to 20mg L$^{-1}$ and 40mg L$^{-1}$ of zinc stress, the root and stem lengths were more than the control group. This was also an expected finding. The reason for this is that in some levels, zinc can be used as a micronutrient (Koc et al., 2012). When it was used with 80mg L$^{-1}$ or more concentration, the root and stem lengths were decreased. In other words, as the concentration of zinc increased, the root and stem lengths of the sunflower seedlings decreased. Decreases between 11-88% in the root lengths of the sunflower seedlings were observed compared to the control plants. Besides, when it was used with 80mg L$^{-1}$ or more, it was observed that in the roots, there were tarnishing and it increased gradually. It is indicated that tarnishing takes place when the suberin level increases and this situation limits the water intake of the plant (Barcelo and Poschenrieder, 1990) (Figure 1).

Nevertheless, statistically significant differences for the effects of zinc stress on the root development was observed above 80mg L$^{-1}$ ($P < 0.05$). A gradual decrease was determined in sunflower seedlings after 80mg L$^{-1}$ depending on the increasing concentrations of zinc ($P < 0.01$). With 320mg L$^{-1}$ concentration, zinc had similar negative effects on the root length of the sunflower seedlings ($P < 0.001$). However, above 160mg L$^{-1}$, zinc had more negative effects on the root and stem length of sunflower seedlings compared to control group (Table 1).

![Fig.1: The views of sunflower seedlings a; control group sunflower samples, b; sunflower samples of exposed to 20 mg L$^{-1}$ Zn stress, c; 40 mg L$^{-1}$, d; 80 mg L$^{-1}$, e; 160 mg L$^{-1}$, f; 320 mg L$^{-1}$, g; 640 mg L$^{-1}$, h; 1280 mg L$^{-1}$](image)

Table 1: Sunflower seedlings were exposed to various zinc (Zn) concentrations (mg L$^{-1}$). Changes in the root length (cm seedling$^{-1}$), dry weight (g seedling$^{-1}$), total protein content (mg ml$^{-1}$) and GTS rate (%).

|            | C   | Zn 20 | Zn 40 | Zn 80 | Zn 160 | Zn 320 | Zn 640 | Zn 1280 |
|------------|-----|-------|-------|-------|--------|--------|--------|--------|
| Root length| 8.5 | 9.5   | 9.0   | 7.5*  | 4.0**  | 2.3*** | 1.5*** | 1.0*** |
| Dry weight | 0.0072 | 0.0073 | 0.0072 | 0.0066* | 0.0058** | 0.0046** | 0.0040** | 0.0028*** |
| Total protein content | 0.0405 | 0.0440 | 0.0410 | 0.0328** | 0.0308** | 0.0249*** | 0.0211*** | 0.0187**** |
The toxic effect of some heavy metals (Pb, Cu, Ni, Zn, Mn and Cd) give damages to the cell structure and physiological activity; it especially results in chlorosis, which is defined with the damage in the activity of chloroplast and decreases of the plant’s size. It also affects the productivity and decreases the amount of chlorophyll and resoluble proteins. As a result, it leads to a negative effect on the production of dry weight (Khurana and Chatterjee, 2001; Bekiaroglu and Karataglis, 2002; Koc et al., 2012). Compared to the control group, the exposure to zinc stress with 80 mg L⁻¹ and more, resulted in a decrease in sunflower seedlings’ dry weight. The negative effect was observed even more in sunflower seedlings’ dry weight with the losses between 8-60% when they were exposed to 80mg L⁻¹ and more concentrations, respectively. Also, there was a consistent relationship between the dry weight and the length of the heavy metal treated root. $R^2$ value of the dry weight-root length for increasing concentrations of zinc treatment were found to be 0.9892 (Figure 2).

![Figure 2: Influence of root dry weight to primary root length and $R^2$ value](image)

Similar to the decreases in the dry weight, the length of root and total soluble protein contents of all the sunflower seedlings effected due to the increase in heavy metal concentration. Similarly, it was indicated that the increase in the concentrations of lead, cadmium and copper causes a decrease in the total protein content of sunflower cucumber and artichoke respectively (Kastori et al., 1992; Soydam et al., 2012; Batir et al., 2016). In this study, when the soluble protein indexes were evaluated in sunflower plants after the applications of zinc solution with different concentrations, the level was found as 0.0405mg L⁻¹ in control group. On the other hand, in 20mg L⁻¹, the total protein level was found to be 0.0440mg L⁻¹ and in 1280mg L⁻¹, it was found to be 0.0187mg L⁻¹. There was an observed increase in 20mg L⁻¹ and 40mg L⁻¹. When it was increased to 80mg L⁻¹ and more concentrations, the protein content was observed to decrease gradually. At the same time, positive correlations were observed between the root total soluble protein content and the root dry weight as well as between the root total soluble protein content and primary root length for zinc treatments in sunflower seedlings. It was seen that root total soluble protein content significantly affected the root dry weight ($R^2 = 0.9828$). In addition, primary root length was significantly affected by the root total soluble protein content in sunflower seedlings exposed to zinc stress ($R^2 = 0.9365$) (Figure 3).

![Figure 3: Influence of root total soluble protein content to primary root length (a) and dry weight (b) and $R^2$ values](image)

**The effect of zinc stress on RAPD profile**

RAPD profile is used to define the genotoxicity in most of the living organisms. There are so many studies about detecting the damage of genotoxic agents on DNA by using RAPD. RAPD methods enable us to examine the relationship between the genotoxic agent and different factors such as concentration and exposure duration. From bacteria to flowery plants, it can be used for so many organisms and it helps to examine multiple samples simultaneously. (Sava, 2000; Atienzaret al., 2002; Liu et al., 2005). For example, Liu et al. (2007); applied
cadmium (Cd) solution in different concentrations to rice 
(Oryza sativa L.) seeds and they suggested that the RAPD 
band patterns have changed in high concentrations. When 
all the other conditions were kept stable, the only change 
that took place occurred in the samples with high metal 
exposure. This situation showed that the genotoxic agent 
cadmium (Cd) has a mutational effect. According to 
RAPD analysis, the reason of observing different band 
profiles in the control is the mutations that occur on the 
genome sites where the primers are bounded on DNA 
structure (Liu et al., 2007). Aksoy et al. (2010); also 
applied copper (Cu) in different concentrations to 
eggplant seeds. In different copper concentrations, the 
grown-up seeds can be observed in terms of their genomic 
structure stability changes by using the RAPD profiles 
(Aksoy et al., 2010); clearly indicated the genotoxic effect of the air pollution and 
heavy metal on lichen samples by using RAPD technic. 
They reported DNA polymorphism induced by 
accumulation of heavy metal in lichens. They also 
expressed that RAPD is more sensitive as they give more 
evidence about DNA damage (Cansaran et al., 2011). In 
another study, Batir et al. (2016); examined the genotoxic effects of lead and copper treatments with different 
concentrations on artichoke seedlings. They reported that 
the lead and copper cause genotoxic effect on the 
genomes of the artichoke and generate polymorphism in 
the RAPD band profiles (Batir et al., 2016). In this study, 
according to the results of RAPD analysis, highly 
important polymorphism is observed in sunflower 
samples subjected to zinc stress. 14 of 20 RAPD primers 
used in this study revealed polymorphic bands that are 
different from the control group of sunflower. OPC09 
(57.2%), OPC08 (55.5%), OPC07 (50%) and OPC11 
(50%) primers showed considerable polymorphic band 
patterns. This showed that these primers are powerful 
indicator for mutagenic effect of heavy metals for 
sunflower plants. Genomic template stability (GTS, %) 
was used to compare the alteration in RAPD profiles with 
the morphological characters which were root length, dry 
weight and total protein content in sunflower seedlings. 
The comparison of GTS (%), root length, dry weight and 
total soluble protein content were calculated according to 
their control value which was set to 100% (Tables 1). When 
compared the GTS rates that were obtained from 
RAPD profiles, the highest rate was 92.85% at 20mg L−1 
zinc concentration. The lowest rate was 83.33% at 
640mg L−1 zinc. These results clearly underline the 
importance of the concentration applied. In addition, it 
was seen that the genomic template stability significantly 
affected the primary root length ($R^2=0.9261$), root dry 
weight ($R^2=0.9358$) and root total soluble protein content 
($R^2 = 0.9216$) (Figure 4).

IV. CONCLUSIONS

In the current study, serious changes were observed in 
sunflower plant both in the population level and 
molecular level when they were exposed to zinc heavy 
metal. Changes in the level of DNA patterns were seen to 
be effective on bio-defense mechanism in sunflower 
plants. Our results indicate that zinc is a genotoxic agent 
for sunflower plant and it can be useful for restoring zinc 
contaminated areas with certain levels. Also, with the 
organism used as the bio-indicator, the biological effects 
of pollution were detected quantitatively in this study.
