Abstract

A comparative *in vitro* study was conducted to ascertain the efficacy of 4 selected antibiotic eye drops against *Staphylococcus aureus* strain isolated from the conjunctiva of a patient diagnosed of bacterial conjunctivitis, and were assayed on the basis of the zone of inhibition. One and two drops volume of the test drugs were inoculated (administered). Results for average inhibition zone for 1 and 2 drops volume was Levofloxacin (26.88 mm), Ciprofloxacin (25.0 mm), Tobramycin (12.5 mm), Gentamicin (7.5 mm) and Levofloxacin (33.12 mm), Ciprofloxacin (30.6 mm), Tobramycin (19.3 mm) and Gentamicin (17.5 mm) respectively with two drops having higher effect than one for Levofloxacin˃ Ciprofloxacin˃ Tobramycin˃ Gentamicin by way of order of susceptibility. The difference in the average zones of inhibition produced by equal volumes of gentamicin and tobramycin and that between ciprofloxacin and levofloxacin both not statistically significant (p˃0.05). Fluoroquinolones showed greater zones of inhibition than the aminoglycosides significantly with levofloxacin more efficacious than ciprofloxacin. One drop prescription is thus recommended. However, if two drops must be prescribed perhaps due to severity of symptoms as the clinician may deem necessary, the drugs should be administered in divided doses. Antimicrobial sensitivity test should be conducted in cases of ocular bacterial infections caused by *Staphylococcus aureus* while treatment with fluoroquinolone especially levofloxacin eye drops as the first line treatment is also suggested

Keywords: Aminoglycosides; Fluoroquinolones; Eye drops; *Staphylococcus aureus*; Bacterial conjunctivitis; Inhibition zone

1. Introduction

The visual system is made up of three essential components: the optics of the eye which focuses an image of the environment on the retina, a system of nerves that transmit the image from the retina to the brain, and the visual cortex which processes the neural impulses [1]. The structure of the eye is highly organized and complex, reflecting the high degree of specialization that is required to support its function [2]. The vascularized nature of the conjunctiva coupled
with its exposure to dust, wind, heat and radiation easily gets infected. *Staphylococcus aureus* is the most common cause of bacterial conjunctivitis, blepharoconjunctivitis and keratoconjunctivitis [3]. *Staphylococcus aureus* is the leading cause of hospital-acquired infections by Gram-positive bacteria [4]. Ocular tissues are vulnerable to *Staphylococcus aureus* infection due to the exposed nature of the eyes. Among the pathogenic bacteria, *Staphylococcus aureus* is the most common cause of ocular infection by Gram-positive bacteria second only to *Pseudomonas aeruginosa*, causing ocular diseases such as conjunctivitis, blepharitis, blepharoconjunctivitis, corneal ulcer, dacryocystitis, orbital cellulitis and dacryoadenitis [5]. The future of modern medicine depends upon effective antibiotics [6].

Antibiotics are among the most frequently prescribed classes of medicines [7]. Antibiotic prescribing by physicians has gained due importance across the globe, mainly because of an increase in antibiotic usage, prevalence of infections, and drug resistances [8]. A report from a study in Nigeria by Anyanwu and Arigbe-Osula (2012) [9], stated that 63.3% and 86.6% of prescriptions containing antibiotics, whereas the rate of antibiotic prescribing was higher for children aged 1–5 years compared to other groups combined 10. According to Todar (2012) [10], a clinically useful antibiotic should be nontoxic to the host and without side effects, have a wide spectrum of activity, non-allergenic to the host, should not eliminate the normal flora of the host, of high bioavailability, chemically stable (long shelf life), inexpensive and easy to produce.

Aminoglycosides are natural or semisynthetic antibiotics derived from actinomycetes. They were among the first antibiotics to be introduced for routine clinical use and several examples have been approved for use in humans [11]. They are highly potent, broad-spectrum antibiotics that interfere with protein synthesis by selectively binding to the 30S [12]. Aminoglycoside antimicrobials were first introduced into clinical application in the middle and last half of the twentieth century primarily to treat severe infections caused by Gram-negative bacteria in animals [13], [14]. Examples include Gentamicin, Amikacin, Tobramycin, Streptomycin, Neo-Fradin, and Neomycin.

Fluoroquinolones (FQs) are counted among broad-spectrum antimicrobials and are used to treat genitourinary, respiratory, gastrointestinal, skin and soft tissue infections [15]. These medicines include ciprofloxacin (Cipro), gemifloxacin (Factive), levofloxacin (Levaquin), moxifloxacin (Avelox), norfloxacin (Noroxin), and ofloxacin (Floxin). Their mechanism of action is based on the drugs' ability to inhibit DNA gyrase and topoisomerase IV, and thus, DNA synthesis [16]. Resistance to fluoroquinolones in clinical isolates of *S. aureus* involves both mutational changes to the topoisomerases that reduce drug binding efficiency and elevated expression of endogenous efflux pumps [17].

This study aimed to ascertain the efficacy of 4 selected antibiotic eye drops against *Staphylococcus aureus* strain isolated from the conjunctiva of a patient diagnosed of bacterial conjunctivitis by way of their antibiotic classifications (Aminoglycosides and Fluoroquinolones).

### 2. Material and methods

#### 2.1. Study area, isolation and identification of test organism

The organism was isolated from the conjunctival swab of a patient diagnosed of bacterial conjunctivitis. An inoculation loop sterilized in Bunsen flame was used to collect the organism, smeared and stained.

*Staphylococcus aureus* was isolated from the conjunctival swab of a student diagnosed of bacterial conjunctivitis in the Optometry Eye Clinic of Imo State University, Owerri, Nigeria and taken for microbiological analysis at the microbiology Laboratory in same institution. The isolate was cultured on nutrient agar for 24 hours. An inoculation loop sterilized in Bunsen flame was used to collect the organism, smeared, stained and identified based on macroscopic features. The result of the vitro growth response of the bacteria to the selected antibiotics as shown by the zones of inhibition (vertical (V) and horizontal (H) diameter) was obtained and recorded where one to two drops of the test drugs were considered.
2.2. Test for antibacterial activity and Assay

Antimicrobial activities were evaluated by the agar well diffusion method as described by Olurinola, (1996) [19] and Minimum Inhibitory Concentration (MIC) by Akinyemi et al., 2005 [20]. Antimicrobial susceptibility was tested on solid media (Nutrient agar) in petri plates the assay. Both Minimum Inhibitory Concentration (MIC) and the Minimum Bactericidal Concentration (MBC) were determined by serial micro dilution assay, suspension of culture for bacterial cells growth was done by preparing 2% Lauria Broth (w/v). The lowest concentrations without visible growth were defined as MICs as reported by Antra and Amla 2012. Microdilution method was used to determine the antibacterial activity of the test drugs against the test organism. Bacterial suspensions were adjusted with sterile saline to a concentration of 1X10^{-7} CFU/ml, while the prepared inoculum stored at 4°C [21].

2.3. Test drugs

The following drugs were purchased from pharmacy stores in Owerri metropolis, Imo State, Nigeria: QUIXIN® (Levofloxacin) ophthalmic solution 0.5% by Fidson Healthcare Plc, Nigeria, CILOXAN® (Ciprofloxacin) ophthalmic solution 0.3% by Alcon, Geneva, Switzerland, GENTALAB® (Gentamicin) ophthalmic solution 0.3% by Famzy Pharmaceuticals, Nigeria and TOBRAMYCIN® ophthalmic solution 0.3% by Bausch & Lomb, Quebec, Canada.

2.4. Statistical analysis

This was performed using SPSS version 17.0 software (IBM-SPSS, Inc., Chicago, IL, USA). Data were compared using the Student’s t-test. A probability (p) value of > 0.05 was considered statistically significant.
3. Results and discussion

Figure 2 Horizontal Inhibition of various antibiotic on S. aureus

Figure 2 shows the trend of the horizontal (H) meridians (diameters) inhibition zones by way of the efficacy of the test drugs against *Staphylococcus aureus*. For 1 drop of drug, it was Levofloxacin (26.88 mm), Ciprofloxacin (25.0 mm), Tobramycin (12.5 mm) and Gentamicin (7.5 mm) respectively. Two drops of drugs gave Levofloxacin (33.12 mm), Ciprofloxacin (30.6 mm), Tobramycin (19.3 mm) and Gentamicin (17.5 mm) respectively.

Figure 3 Vertical Inhibition of various antibiotic on S. aureus

Results for trend of the vertical (V) meridians (diameters) inhibition zones by way of the efficacy of the test drugs against *Staphylococcus aureus* had a slight change, for 1 drop of drug, it was Ciprofloxacin (27.5 mm), Levofloxacin (26.88 mm), Tobramycin (11.88 mm) and Gentamicin (6.88 mm) respectively, while two drops of drugs gave same trend like that of the horizontal zone with Levofloxacin (36.88 mm), Ciprofloxacin (31.88 mm), Tobramycin (20.0 mm) and Gentamicin (15.63 mm) respectively – Figure 3.

Figures 2 and 3 however shows that 2 drops of the various test drugs were more efficacious than 1 drop.
Tobramycin appears to be more effective against *Staphylococcus aureus* than gentamicin for equal volumes of drugs studied. Levofloxacin appears to be more effective against *S. aureus* than gentamicin for equal volumes of drugs used. For equal volumes of the drugs, the fluoroquinolones appear to more effective than aminoglycosides against *Staphylococcus aureus in vitro* – Figure 4.

Comparatively, in terms of the classes of the antibiotics, the zones of inhibition produced by 1 and 2 drops of aminoglycosides (gentamicin and tobramycin) measured in both vertical and horizontal meridians had averages of 5.75 mm, 13.25 mm, 9.75 mm and 15.75 mm respectively. Those for the fluoroquinolones (ciprofloxacin and levofloxacin) were 20.00 mm, 25.00 mm, 21.50 mm and 26.00 mm respectively – Figure 4. There was no significant difference in the average efficacy of tobramycin and gentamicin as well as that of levofloxacin and ciprofloxacin against *Staphylococcus aureus in vitro* when two drops and one drop volumes are administered (P< 2.447). Results further showed that the *Staphylococcus aureus* strain was resistant to one drop of tobramycin but susceptible to two drops of tobramycin. However, there was significant difference in the average efficacy of the fluoroquinolones and aminoglycosides against the randomly selected *Staphylococcus aureus* strain *in vitro* (P>2.447).

Our study also showed that for equal volumes of the brands of aminoglycosides used, tobramycin proved to be more effective in inhibiting the growth of *Staphylococcus aureus* than gentamicin although with no significant difference. Biswas et al., (2011) [22] listed tobramycin as potent against gram-negative bacteria whereas, *Staphylococcus aureus* is gram-positive. This highlights the need for further research to evaluate the efficacy of tobramycin against all strains of *Staphylococcus aureus* and the mechanism involved. Levofloxacin was more efficacious than ciprofloxacin against the *S. aureus* strain *in vitro* for equal volumes of the drugs. This supports the findings of (Davis & Bryson, 1994) [23] and Graves et al., 2001 [24].

There was substantial difference in efficacy when one drop volume and two drops volume were compared for all the test drugs as 2 drops had higher effect than 1, following Levofloxacin> Ciprofloxacin> Tobramycin> Gentamicin, in order words, considering the classes: fluoroquinolones > Aminoglycosides. However, one drop volume should be prescribed so as to avoid wastage considering the capacity of the conjunctival cul-de-sac. If two drops must be prescribed (perhaps due to severity of symptoms) as the clinician may deem necessary, then the drugs should be administered in divided doses.

## 4. Conclusion

Fluoroquinolones are more efficacious than the aminoglycosides against *Staphylococcus aureus* isolated from a conjunctivitis patient (*in vitro*). Two drops had higher effect than one, (Levofloxacin> Ciprofloxacin> Tobramycin> Gentamicin). One drop should be prescribed so as to avoid wastage considering the capacity of the conjunctival cul-de-sac. If two drops must be prescribed (perhaps due to severity of symptoms) as the clinician may deem necessary, then the drugs should be administered in divided doses.
