Abstract.

The FASTSUM Collaboration has calculated several quantities relevant for QCD studies at non-zero temperature using the lattice technique. We report here our results for the (i) interquark potential in charmonium; (ii) bottomonium spectral functions; and (iii) electrical conductivity. All results were obtained with 2+1 flavours of dynamical fermions on an anisotropic lattice which allows greater resolution in the temporal direction.

1. Introduction

The Particle Data Book [1] is a repository of particle physics knowledge, and yet it contains no entries on the deconfined phase of QCD. We present here some lattice calculations of phenomena in the quark-gluon plasma (QGP) phase with the ultimate aim of addressing this omission.

The lattice approach is based on the non-perturbative study of correlation functions of operators calculated in a background of glue and dynamical (sea) quarks using the imaginary time (i.e. Euclidean) formulation\textsuperscript{1}. For instance, to study the $\eta_c$ system, correlators, $\langle C(\tau) \rangle$, of the operator $J = \gamma_5 c$ are determined ($c$ is the charm quark field). Each state $i$ which has the same quantum numbers as $J$ (and therefore can be excited by it) contributes a term $\sim e^{-M_i \tau}$ to $\langle C(\tau) \rangle$, where $M_i$ is the mass of state $i$. For large $\tau$, only the ground state remains, and its properties can be determined.

While the lattice technique has had many successes in calculating phenomenologically relevant quantities at zero chemical potential, $\mu$, particularly in the confined phase of QCD, it has a significant limitation for $\mu > 0$. This is the well-known “sign problem” which has haunted efforts to extend our knowledge into the entire $(T, \mu)$ plane\textsuperscript{2}.

\textsuperscript{1}For a general introduction to lattice gauge theory see [2], and non-zero temperature reviews, see [3, 4].
\textsuperscript{2}For reviews of the sign problem, see [5].
In this talk, I will discuss three lattice results obtained by the FASTSUM Collaboration at $\mu = 0$ and non-zero temperature, $T$, above and below the deconfining temperature, $T_c$, all produced on our 2+1 flavour, anisotropic lattices. These topics are a calculation of the potential in the charmonium system (Sec.2), bottomonium spectral functions (Sec.3), and a determination of the electrical conductivity of QCD as a function of $T$ (Sec.4).

This work uses lattice simulations with the parameters in Table 1 and a carefully crafted action with reduced lattice artefacts [6]. Anisotropic rather than isotropic lattices provide a distinct advantage due to the finer temporal resolution and correspondingly larger sampling of the correlator, $C(\tau)$. This is particularly significant in the $T > 0$ case where the temporal extent is limited to $0 \leq \tau \leq 1/T$. Our $T_c$ value is obtained from the Polyakov Loop.

| $N_s$ | 32 | 24 | 24 | 24 | 32 | 24 | 24 | 24 | 32 |
|------|----|----|----|----|----|----|----|----|----|
| $N_\tau$ | 48 | 40 | 36 | 32 | 32 | 28 | 24 | 24 | 20 |
| $T$(MeV) | 117 | 141 | 156 | 176 | 201 | 201 | 235 | 235 | 281 |
| $T/T_c$ | 0.63 | 0.76 | 0.84 | 0.95 | 1.09 | 1.09 | 1.27 | 1.27 | 1.52 |

Table 1. Lattice parameters used where $N_{(s)\tau}$ is the number of sites in the spatial (temporal) direction. Our spatial and temporal lattice spacings are $a_s = 0.1227(8)$ and $a_\tau = 0.0351(2)$ fm.

2. Charmonium potential

The interquark potential in charmonium is of great interest to phenomenologists modelling the QGP phase in heavy ion collisions. Knowledge of this potential aids our understanding of the $J/\psi$ system, and the extent to which states become unbound with increasing temperature.

Lattice calculations of the finite temperature interquark potential have, until recently, been restricted to the static (i.e. infinitely heavy) quark limit [7]. On the other hand, the finite-mass interquark potential has been calculated at $T = 0$ [8] using the method developed by the HAL QCD collaboration for internucleon potentials [9]. This method first calculates the correlator, $C(\tau)$, of the electrical conductivity of QCD as a function of $T$ (Sec.4).

In our case, we consider non-local operators of (charm) quark fields, $J(x, r) = c(x)\Gamma U(x, x + r)\bar{c}(x + r)$, where $\Gamma$ is an appropriately chosen Dirac (gamma) matrix, and $U(x, x + r)$ is the gauge connection between $x$ and $x + r$ [10]. The correlation function of these operators is

$$C(r, \tau) = \sum_x \langle J(x, r)J(0) \rangle = \sum_i \frac{\psi_i(r)\psi_i^{\dagger}(0)}{2M_i} e^{-M_i\tau},$$

where the second sum is over the states $i$. Following [11], $C(r, \tau)$ satisfies the Schrödinger equation which can then be used to extract the potential.

As usual, the potential can be decomposed into the central, $V_C(r)$, and the spin dependent, $V_S(r)$, terms, $V_T(r) = V_C(r) + s_1 \cdot s_2 V_S(r)$, where $s_{1,2}$ are the spins of the charm quarks. In Fig.1 (Left), we show the charmonium central potential, $V_C(r)$, thus obtained at various temperatures above and below the deconfining temperature. We use $N_s = 24$ in this work. As can be seen, there is a clear temperature dependence in our calculated potential which becomes less confining as $T$ increases. In Fig.1 (Right) $V_S(r)$, is plotted showing a repulsive core with a temperature variation at large distances.

3. Bottomonium spectral functions

In this section we discuss our studies of bottomonium at $T > 0$. Recent results from CMS show that the 1S and 2S/3S $\Upsilon$ states have different relative multiplicities in Pb-Pb compared...
to p-p collisions at the LHC [12]. This result confirms the picture, originally proposed in the charmonium system, in which the higher mass states in quarkonium are the first to become unbound as the temperature increases beyond $T_c$ [13].

We have performed lattice simulations of the bottomonium system using an $O(v^4)$ NRQCD lattice action [14] to represent the $b$-quarks. This extends our earlier work [15]. NRQCD is an approximation obtained from QCD as a velocity expansion in $v/c$, and is thus applicable for $b$-quarks. The advantages of NRQCD over the (exact) relativistic quark formulation are two-fold. There is no periodicity in time which complicates the correlation function: in the relativistic case, backward movers effectively half the number of time points that carry independent information. The lack of these thermal boundary effects means that the NRQCD quarks should be viewed as test colour charges moving in a thermal bath of dynamical light quarks and gluons. Secondly, the solution of the NRQCD propagator is an initial value problem which is much easier to solve than the matrix inversion required in the relativistic case. Thus, for a given computer resource, much higher statistics can be achieved in the NRQCD case.

The spectral function, $\rho(\omega)$, can be defined from the two-point correlation function, $C(\tau)$, of bottomonium operators via

$$C(\tau) = \int \rho(\omega) K(\tau, \omega) d\omega,$$

where in the NRQCD case the kernel is $K(\tau, \omega) = \exp(-\omega \tau)$. In principle, the spectral function contains complete information on the states in the channel considered. For a stable particle of mass $M$, $\rho(\omega) \propto \delta(\omega - M)$. For a resonance, this $\delta$-function broadens acquiring a non-zero width, and if the state becomes unbound, the spectral feature disappears.

We have used the Maximum Entropy Method (MEM), a Bayesian technique, to de-convolve eq. (2) to extract $\rho(\omega)$ [16]. The results for the $S$-wave ($\Upsilon$) channel and $P$-wave ($\chi_{b1}$) channels are shown in Fig. 2, all obtained with $N_s = 24$. There is a distinct temperature dependence in both channels. While the $\Upsilon$ ground state ($1S$) peak is seen to decrease with $T$, it remains a distinct (i.e. bound) feature up to $T \approx 1.90 T_c$. However, the excited state ($2S$) peak seems to disappear for $T \gtrsim T_c$. This agrees with the experimental result obtained by the CMS collaboration [12]. These results contrast with the $\chi_{b1}$ case where the ground state ($1P$) appears to melt at $T \approx T_c$, see Fig. 2 (Right).

4. Electrical conductivity

We now discuss our calculation of the electrical conductivity, $\sigma$ [17]. Transport coefficients such as $\sigma$ are of special relevance for understanding the bulk properties of the fireball in relativistic heavy-ion collision experiments. Typically, they can be determined from the zero energy limit of the appropriate spectral function, i.e. $\lim_{\omega \to 0} \rho/\omega$. In the case of the conductivity, the correlator to consider is that of the electromagnetic current of quark flavour $f$,

$$C_{\text{em}}^{-1}(\tau, \omega) = \sum_i \int d^3x \langle j_{i,\text{em}}^e(\tau, x) j_{i,\text{em}}^e(0, x) \rangle$$

with

$$j_{i,\text{em}}^e(x) = e \sum_f q_f j_{i,f}^f(x),$$

where $e$ is the electron’s charge, $q_f = \frac{2}{3}, \frac{1}{3}$, is the fractional charge and $j_{i,f}^f \sim \bar{\psi}_{i} \gamma_i \psi_{f}^f$ the number density current of quark field $\psi_{f}^f$. In our case [17] we use the conserved lattice vector current (i.e. $\partial_{\mu} j_{\mu}^f = 0$) which means we do not have to renormalise our results. We again use MEM to invert the correlator to extract the corresponding $\rho_{\text{em}}^\omega(\omega)$, see Eq(2), but this time with the relativistic kernel $K(\tau, \omega) = \cosh[\omega(\tau - 1/2T)]/\sinh[\omega/2T]$. 

Figure 2. The NRQCD Bottomonium S-wave (Left) and P-wave (Right) spectral functions.

Figure 3. The (light-quark) electromagnetic spectral function, $\rho_{\text{em}}^\omega(\omega)$, showing the conductivity signal in the $\omega \to 0$ limit. $C_{\text{em}} = 5/9e^2$ for two light flavours.

Figure 4. The conductivity, $\sigma$, as a function of temperature. As well as the results from our work, quenched ($N_f = 0$) [18, 19] and dynamical results [20] are also shown.
The conductivity is obtained via the Kubo relation,
\[ \frac{\sigma}{T} = \frac{1}{6T} \lim_{\omega \to 0} \rho^{\text{im}}(\omega). \] (4)

Fig.3 shows \( \rho^{\text{im}}(\omega) \) around \( \omega \approx 0 \) for three temperatures spanning \( T_c \). There is a clear non-zero intercept at \( \omega = 0 \) for \( T \gtrsim T_c \), indicating a conductivity signal. In Fig.4, we present our \( \sigma \) values for all the \( T \) values we studied. The dimensionless ratio \( \sigma/T \) increases across the transition temperature. Results from three other published works are also shown [18, 19, 20].

5. Conclusion

In this talk, I have summarised our collaboration’s lattice calculations showing that the charmonium potential becomes less binding with higher \( T \), that the \( \Upsilon(1S) \) state survives above \( T_c \) but the \( \Upsilon(2S) \) and \( \chi_{b1} \) don’t, and that the conductivity increases with \( T \) across the transition.
