Weak lensing by voids in weak lensing maps

Christopher T. Davies, Marius Cautun and Baojiu Li

ABSTRACT

Cosmic voids are an important probe of large-scale structure that can constrain cosmological parameters and test cosmological models. We present a new paradigm for void studies: void detection in weak lensing convergence maps. This approach identifies objects that relate directly to our theoretical understanding of voids as underdensities in the total matter field and presents several advantages compared to the customary method of finding voids in the galaxy distribution. We exemplify this approach by identifying voids using the weak lensing peaks as tracers of the large-scale structure. We find self-similarity in the void abundance across a range of peak signal-to-noise selection thresholds. The voids obtained via this approach give a tangential shear signal up to \(\sim 40\) times larger than voids identified in the galaxy distribution.

Key words: gravitational lensing: weak – methods: data analysis – cosmology: theory – large-scale structure of Universe.

1 INTRODUCTION

The large-scale structures of the Universe, collectively called the cosmic web, describe the matter distribution in our Universe in the forms of structures such as voids, sheets, filaments, and knots. These structures result from the anisotropic gravitational collapse of matter on cosmic scales. These components are intertwined in a complex web where the knots form at the intersections of filaments, filaments form at the intersections of sheets, and voids occupy the underdense space between all three (Bond, Kofman & Pogosyan 1996).

Voids, which represent large regions mostly devoid of matter and galaxies, have attracted a lot of interest as powerful probes of cosmological parameters (Lavaux & Wandelt 2012; Hamaus et al. 2016), dark energy (Li 2011; Bos et al. 2012; Pisani et al. 2015), and dark matter (Massara et al. 2015). Voids are especially useful for testing cosmological models that make environmentally dependent predictions, such as the fifth force of modified gravity theories which, while screened in high-density regions, attains maximum values in voids (Clampitt, Cai & Li 2013; Barreira et al. 2015; Cai, Padilla & Li 2015; Baker et al. 2018; Falck et al. 2018). The largest constraining power of voids comes from measuring their total matter content (e.g. Cautun et al. 2018), which can be achieved via gravitational lensing (Melchior et al. 2014; Clampitt, Jain & Sánchez 2016; Gruen et al. 2016; Cai et al. 2017; Sánchez et al. 2017), redshift space distortions (Hamaus et al. 2015; Cai et al. 2016) as well as the integrated Sachs–Wolfe effect in the cosmic microwave background (Granett, Neyrinck & Szapudi 2008; Nadathur 2016). In particular, weak lensing (WL) measurements using upcoming large area and deep imaging surveys such as Euclid and LSST will result in tight constraints on the mass profile of voids (Krause et al. 2013; Cautun et al. 2018).

Theoretically, voids correspond to low-density regions in the large-scale matter field (Sheth & van de Weygaert 2004; van de Weygaert & Platen 2011; Aragon-Calvo & Szalay 2013). However, because the full mass distribution is not easily observable, observational studies typically identify voids using the galaxy distribution (e.g. Nadathur 2016). Due to the sparsity of galaxy tracers and their bias, which depends on environment (Neyrinck et al. 2014), the relation between matter and galaxy voids is a complex one, with galaxy voids being typically less underdense than would have otherwise been identified using the full matter density field. This could potentially weaken the lensing signals (which are produced by the total matter) from galaxy voids, and, due to difficulties in simulating galaxies in cosmological volumes, it is also more challenging to test cosmology using galaxy void properties such as abundances and sizes (see, e.g. Cautun et al. 2018).

In this work, we propose a new paradigm for void studies: the identification of voids from weak-lensing convergence maps, which we refer to as VOLEs (VOIds from LEnsing). The convergence field represents the projected line-of-sight density field weighted by the lensing kernel, and thus the identified underdensities correspond to voids in the projected density field (for example Chang et al. 2018 have shown that the deepest minima of the convergence field have good correspondence to galaxy voids). This approach represents a simple way of finding voids that relates directly to our theoretical understanding of voids as underdensities in the total matter field. As void lensing is a key observable, it is only natural to identify voids and extract their lensing signal from the very same observations, such as a convergence map. VOLEs not only help avoid some of the disadvantages of galaxy voids, but also allow for a more complete exploitation of lensing maps by naturally combining VOLEs with other statistics, such as WL peaks and Minkowski functionals.

There are many void finders in the literature (e.g. see the void comparison project of Colberg et al. 2008) and here we choose to...
illustrate our methodology using the tunnel finding method (Cautun et al. 2018), but, in principle, many of the previous void finding approaches can be applied to the lensing convergence maps by using the convergence field itself, rather than using peaks as tracers. Our choice of tunnels is based on the Cautun et al. (2018) and Paillas et al. (2018) studies which find that WL by tunnels identified in the galaxy distribution is the most promising method for testing a wide range of modified gravity theories.

2 METHOD

2.1 N-body and ray-tracing simulations

The WL maps used in this analysis are made using an analytical on-the-fly ray tracing algorithm, RAY-RAMES (Li et al. 2011; Barreira et al. 2016), which is inbuilt in the publicly available N-body and hydrodynamical adaptive mesh refinement simulation code RAMES (Teyssier 2002). The N-body part of the evolution is done using the default RAMES code. To construct the first map, five independent realizations of simulations evolving 1024$^3$ particles in a 512$^3$ Mpc box are tiled together to form a light cone up to a source redshift $z_s = 1$ (see fig. 1 of Barreira et al. 2016 for an illustration). The second map is constructed from the same box repeated five times. The cosmological parameters adopted are $\Omega_m = 0.32$, $\Omega_\Lambda = 0.68$, and $H_0 = 67$ km s$^{-1}$ Mpc$^{-1}$. The two WL convergence maps cover a field of view of $10 \times 10$ deg$^2$ with a resolution of 2048$^2$ pixels.

In order to use information from separate maps in conjunction with each other, we respectively subtract the mean convergence value of each map, to give us zero-mean convergence maps.

2.2 Galaxy shape noise

The convergence field is determined observationally by averaging over a large number of source galaxies, which, due to their intrinsic ellipticity, lead to measurement uncertainties. This effect is known as galaxy shape noise (GSN) and can be a main uncertainty source on small angular scales. To allow our method to be interpreted in the context of observations, we generate WL maps with added GSN and compare the VOLEs identified with and without GSN. For each pixel of the WL maps, we add GSN by drawing from a Gaussian with standard deviation

$$\sigma^2_{\text{pix}} = \sigma^2_{\text{gal}} / 2\theta^2_{\text{pix}} n_{\text{gal}},$$

where $\sigma_{\text{gal}}$ is the dispersion of the source galaxy intrinsic ellipticity, $\theta_{\text{pix}}$ the angular width of each pixel, and $n_{\text{gal}}$ the number density of source galaxies. Here we use $\sigma_{\text{gal}} = 0.4$ and $n_{\text{gal}} = 40$ arcmin$^{-2}$, corresponding to LSST (LSST Science Collaboration et al. 2009).

2.3 Peak extraction

In a first step, we identify peaks in the convergence map. In order to suppress GSN, we smooth the convergence map using a Gaussian window with a smoothing scale, $\theta_{\text{sm}}$, of 2.5 arcmin (unless otherwise stated). We define a peak as a pixel whose convergence value is greater than that of its eight neighbours. We also trim the peaks in each map within one smoothing length of the edge of the map to exclude the boundary effects of smoothing a finite map. Each peak is characterized by the lensing convergence at its position, which we express as a signal-to-noise ratio (SNR), $v = \kappa / \sigma$, where $\sigma$ is the standard deviation of the smoothed convergence maps, which is 0.011 and 0.012 for the maps without and with GSN, respectively.

2.4 Void identification

We identify voids using the tunnel finding algorithm of Cautun et al. (2018), which is so-named because it has been developed to find regions in the projected distribution of galaxies that do not contain any galaxies. The method can easily be extended and applied to the WL field by identifying the largest circles that are devoid of peaks. Thus, the tunnels correspond to circles in the 2D convergence map that contain no WL peaks.

The tunnels are obtained by first constructing a Delaunay tessellation with its vertices chosen to be the WL peaks. By definition, the circumsphere of every Delaunay triangle does not enclose any WL peak. The WL peaks, which define the triangle, reside directly on its circumsphere. Thus, each circumsphere represents a candidate tunnel with radius, $R_v$, and centre given by that of the corresponding circumsphere. We further discard any tunnels whose centres are found inside a larger tunnel. A visualization of the tunnels found from the WL peak catalogues in one of our maps is shown in Fig. 2.

2.5 Calculating void profiles

We calculate the convergence profiles of voids by using annuli of thickness $R_v / N_{\text{bin}}$, where $R_v$ is the void radius and $N_{\text{bin}} = 20$, and...
then stack all the voids in terms of the scaled radial distance, \( r/R_v \).

To get better statistics, we average over both lensing maps.

The tangential shear profile \( \gamma_t(r) \) is calculated from the convergence profile using

\[
\gamma_t(r) = \bar{\kappa}(<r) - \kappa(r); \quad \bar{\kappa}(<r) = \frac{1}{\pi r^2} \int_0^r 2\pi r' \kappa(r') \, dr',
\]

where \( \kappa(r) \) denotes the convergence at the radial distance \( r \) and \( \bar{\kappa}(<r) \) the mean enclosed convergence within \( r \).

All of our uncertainties, including those of the convergence and shear profiles, are estimated using bootstrap sampling. For each of the two maps, we generate 100 bootstrap resamples, which we then combine and quote the uncertainties obtained by taking the 16th and 84th percentiles of these resamples.

## 3 RESULTS

Fig. 2 shows that, as the \( \nu \) threshold increases, the WL peaks are more spread out, and less numerous, resulting in larger voids. This is as expected because high-SNR peaks generally correspond to more massive structures or more structures aligned along the line of sight, which are rarer (e.g. Liu & Haiman 2016). The third panel shows how adding GSN can slightly alter the void catalogue. The dependence of void size on \( \nu \) is quantitatively confirmed in the cumulative void radius distribution given in Fig. 3, which shows that the \( \nu > 1 \) void catalogue has more small voids and fewer large voids, with none above \( R_v \sim 0.7 \) deg, while the \( \nu > 3 \) catalogue has fewer small voids and more large voids with radii up to \( R_v \sim 1.1 \) deg. Again we can see that GSN has a small impact on the voids size distribution, where the addition of spurious peaks tend to slightly reduce the size of the voids. The inlay plot shows a universal relation in the void abundance for catalogues with \( \theta_p = 1 \) arcmin, where \( R_v \) is scaled by the mean peak separation, \( \theta_p \), and \( n(>R_v) \) is divided by the mean peak number density, \( n_p \), of the corresponding peak catalogue. The shaded regions show 1σ uncertainties.

SNR thresholds (see the inlay panel of Fig. 1), and we will present a detailed analysis on this, based on larger and more realistic lensing maps, in a forthcoming work.

### 3.1 Void convergence profiles

Fig. 4 shows the convergence profiles as a function of scaled radial distance, \( r/R_v \), averaged over all voids in both lensing maps. The profiles are plotted up to twice the void radius to show how, at large distances, they return to background levels (which we have set to be 0). Each curve corresponds to one of the three void catalogues. For \( r \leq 0.75 R_v \), we find negative convergence values, which indicates that the voids are underdense in those regions. Interestingly, the \( \nu > 3 \) void catalogue has the least underdense voids. This is to be expected, since the \( \nu > 3 \) voids are the largest and can enclose inside them slightly overdense regions, i.e. with \( \kappa > 0 \). As the peak SNR threshold used to identify voids decrease, the voids become smaller, they enclose fewer overdense regions and thus have lower overall \( \kappa \) values. The maximum convergence is achieved at \( r = R_v \).
and all three void catalogues have roughly similar maximum values. At even larger radii, the convergence profiles decrease towards the mean background value of \( \kappa = 0 \). Of the three catalogues, \( \nu > 3 \) voids take the longest to reach the background value, which is a manifestation of the fact that the large peak values that define the boundary of \( \nu > 3 \) voids are typically found in large-scale overdense regions. Voids identified using high-SNR peaks, i.e. \( \nu \gtrsim 2 \), have the same profiles in WL maps with and without GSN, but differences appear when using low-SNR peaks, i.e. \( \nu \lesssim 1 \), where GSN can lead to spurious peaks, and thus spurious voids.

A final feature of the convergence profiles is that the width of the convergence maximum somewhat decreases as we increase the \( \nu \) threshold of the WL peaks used for finding voids. This is due to the profiles being plotted against the rescaled distance, \( r/R_s \), rather than the physical distance, \( r \). The \( \nu > 2 \) and 3 voids actually have wider convergence maxima when expressed as a function of \( r \), but this larger width is overcompensated by their even larger radii which results in a narrower maxima when expressed in rescaled distances.

### 3.2 Tangential shear profiles

Fig. 5 shows the tangential shear profiles of the VOLES, calculated using equation (2). These profiles are qualitatively similar with the tangential shear of galaxy voids (e.g. Cautun et al. 2018) and show a maximum signal at \( r = R_s \). The maximum signal has a negative value, indicating that voids lead to diverging lensing, similar to a concave lens. Like the convergence profiles, larger \( \nu \) thresholds reduce the width associated with the maximum tangential shear signal, while the height and position of the maximum signal are almost independent of the \( \nu \) threshold from \( \nu > 2 \). The shear signals are very similar for the case with GSN, with the greatest deviation at the lower \( \nu \) threshold, \( \nu > 1 \) due to spurious peaks from GSN, which create spurious voids.

The error bars for the tangential shear profiles are smaller than those for the convergence profiles (see Fig. 4). The uncertainty in the convergence profile is dominated by modes many times larger than the void size, which determines on average a systematic shift up or down between the convergence profiles of voids some distance apart. We checked that the voids in different regions of the lensing map have the same convergence profile up to some constant shift in \( \kappa \) values. In contrast, the tangential shear profiles are only sensitive to the shape of the convergence profiles, and are not affected by a constant shift of the latter. Thus, given one WL peak catalogue, different VOLES have very similar lensing profiles, however the profiles show a weak dependence on the \( \nu \) threshold used to define the peak catalogue. It remains to be seen whether there is a strong cosmological model dependence of the VOLES \( \gamma \) profiles, which we leave for future work.

Fig. 5 also compares the VOLES tangential shear profiles to results from other void definitions used in previous works. We compare the VOLES with three types of voids identified in the galaxy distribution: 3D watershed voids (WVF, Platen, van de Weygaert & Jones 2007), fixed-aperture cylinders along lines of sight with low-projected galaxy number densities (troughs; Gruen et al. 2016) and tunnels (the same as the method used in this work but applied to galaxy fields). These three void catalogue are obtained from a \( z = 0.5 \) halo occupation distribution galaxy catalogue that matches the clustering of SDSS-CMASS which has a galaxy number density, \( n_g \approx 3 \times 10^{-3} h^3 \) Mpc\(^{-3} \) (see Cautun et al. 2018, for more details). This represents a typical galaxy catalogue at redshift, \( z = 0.5 \). We take the WL signals of the galaxy voids from Cautun et al. (2018), and we rescale them to match our source galaxies redshift, \( z_s = 1 \).

We find that the maximum \( \gamma \), signal of VOLES is roughly twice as large as tunnels identified from a galaxy field, and about 10 and 40 times larger than the signals of troughs and WVF voids, respectively. The stronger lensing signal in VOLES is not surprising since the WL peaks are taken straight from the convergence field itself, which is directly related to the projected total matter distribution. The projected galaxy number density used to identify the Cautun et al. tunnels and troughs is \( \sim 500 \) gal deg\(^{-2} \) and is much larger than that used for the VOLES catalogues (see Fig. 1). We find that using higher number density peak catalogues, which could be obtained with a smaller smoothing scale and smaller GSN, results in VOLES with an even higher tangential shear signal and thus increases further the differences between VOLES and galaxy tunnels.

### 4 CONCLUSIONS AND FUTURE WORK

Cosmic voids are becoming an increasingly important cosmological probe. While theoretical studies usually focus on voids identified...
from the dark matter field, in observations galaxies are usually used as tracers to find voids. Here, we have proposed an alternative: to identify voids in the WL convergence field (dubbed VOLES), which, since it represents the line-of-sight projected matter distribution, is conceptually closer to identifying voids as underdensities in the matter distribution. This opens a new window for exploring the cosmic mass distribution and, in particular, for designing novel environment-sensitive cosmological tests.

As an example, we identified VOLES by applying the tunnel algorithm of Cautun et al. (2018) to the WL lensing peak distribution, and investigated several properties, including their abundance, convergence and tangential shear profiles. Using peaks with lower SNR leads to finding smaller voids, which are on average more underdense. The void convergence profiles, which are indicative of the projected matter density inside and around the voids, are negative for \( r \leq 0.75R_v \), which corresponds to line-of-sight underdensities, and show a sharp overdense peak at the void edge, \( r = R_v \). In terms of tangential shear profiles, the VOLES show a maximum signal at \( r = R_v \), with the maximum signal height somewhat independent of the peak catalogue used to identify the voids. However, the width of the tangential shear signal decreases when using peaks corresponding to a higher SNR threshold. We found that the amplitude of the maximum signal in the tangential shear profiles for the VOLES is roughly twice as large as that of voids generated using the same void finder (tunnels) but by using galaxies as tracers. The amplitude is more than an order of magnitude larger compared to those corresponding to galaxy voids identified using other algorithms (tunnels and WVF voids). This shows the benefit of using a more reliable tracer of the projected total matter field.

The method introduced here represents a new avenue to identify 2D voids rather than a new void-finding algorithm, in the sense that many, if not all, existing void finders (tunnels, spherical void finders, WVF, ZOBOV, etc.) can be applied to the WL convergence maps. Indeed, in principle one can use the WL convergence field itself (i.e. not just the peaks from it) as a tracer field for void identification. The study of void identification and void lensing from the same WL observation is also convenient in practice, because there is no need for foreground galaxies, whose redshifts are hard to measure accurately and can be affected by the peculiar velocities of the galaxies. Instead, the particular lensing map that is used to study void lensing is expected to offer sufficient information for locating those very voids. With the upcoming WL surveys (HSC, EUCLID, LSST, etc.) which offer lensing maps with increasing sky coverage, we hope that this approach will take us a step forward in extracting information from such maps in a maximal way.

Unlike galaxy voids, for VOLES it is also possible to use void abundance to discriminate different models as there is no ambiguity in modelling the galaxy populations for these models. The universal scaled void abundance shown in Fig. 3 implies that it is possible to find generic simulation-calibrated fitting formulae for these void properties (e.g. Hamaus, Sutter & Wandelt 2014) which can be used as theoretical templates in cosmological tests. For the latter purpose, it is also critical to test the VOLES void finding method in real weak lensing data sets to understand how observational systematics and galaxy formation physics can affect the void properties. These possibilities will be investigated in follow-up studies.

ACKNOWLEDGEMENTS

We thank Alexandre Barreira for providing the lensing maps used in the analysis of this work, and Yanchuan Cai, Chieh-An Lin, Masato Shirasaki for useful comments. CTD is supported by a Science and Technology Facilities Council (STFC) PhD studentship through grant ST/R504725/1. MC is supported by STFC grant ST/P000541/1.
