PHF7, a novel male gene influences female fecundity and population growth in *Nilaparvata lugens* Stål (Hemiptera: Delphacidae)

Lin-Quan Ge¹, Ting Xia¹, Bo Huang¹, Hao-Tian Gu¹, Qi-Sheng Song², Guo-Qing Yang¹, Fang Liu¹ & Jin-Cai Wu¹

PHF7 exhibits male-specific expression in early germ cells, germline stem cells and spermatogonia in insects, and its expression promotes spermatogenesis in germ cells when they are present in a male soma. However, the influence of male-specific PHF7 on female reproductive biology via mating remains unclear. Thus, we investigated the potential impacts of male PHF7, existed in seminal fluid of *Nilaparvata lugens* (*Nl*PHF7), on fecundity and population growth via mating. Our results revealed that suppressing male *NlPHF7* expression by RNAi led to decreases in body weight, soluble accessory gland protein content, arginine content, and reproductive organ development in males, resulting in significant reduction of oviposition periods and fecundity in females, and significant decrease in body weight, fat body and ovarian protein content, yeast-like symbionts abundance, ovarian development and vitellogenin gene expression in their female mating partners. Similarly, suppression of *NlPHF7* expression in males mated with the control female reduced population growth and egg hatching rate, but did not influence gender ratio. We infer that *NlPHF7* play a role important in stimulating female fecundity via mating. This study provides valuable information by identifying a potentially effective target gene for managing BPH population through RNAi.

In insects, male accessory gland (MAG) proteins are essential components of seminal fluids that act in influencing post-mating changes in female behavior, such as reduced sexual receptivity¹, increased oviposition² and increased sexual refractory periods³. MAG proteins act in sperm transport and storage, and because they also include antimicrobial peptides, they provide prophylactic protection for the female reproductive tract, activation and nourishment of sperms until fertilization⁴. Insect mating systems are evolved and tremendously varied traits. For a single example, MAG proteins do not induce refractoriness in all species⁵. MAG proteins also influence post-mating female physiology, stimulating oogenesis, ovulation and oviposition. The idea that males can influence their sexual partners via constituents of their seminal fluids is a strong insight into understanding the mating systems of many animal species and may have practical relevance for insect pest management⁶, especially for agricultural migratory insect pests.

The brown planthopper (BPH), *Nilaparvata lugens* (Stål) is a serious pest of rice crops in Asia and Australia⁷ and a classic example of an insecticide-induced resurgent pest⁸. Previous studies have demonstrated that insecticide treatments enhanced BPH MAG protein content⁹. In comparison with untreated males, females mated with insecticide-treated males led to increased fecundity⁹. The insecticides exerted effects on BPH reproduction appear to operate through a PHD finger protein 7 (*NIPHF7*) gene because it was up-regulated after triazophos (tzp)-treatment⁶. Unfortunately, the underlying relationship between insecticide-induced *NIPHF7* up-regulation and female reproduction has not been well elucidated. Nonetheless, there is a growing interest in exploring it as a BPH gene for its broad importance in animals and *Drosophila melanogaster*. PHF7, also known as testis development NYD-SP6, was discovered in research designed to identify new testicular development or spermatogenesis¹¹. This work with a human testicular cDNA library yielded a gene encoding a protein-named NYD-SP6,

¹School of Plant Protection Yangzhou University, Yangzhou, 225009, P.R. China. ²Division of Plant Sciences, University of Missouri, 1-31 Agriculture Building, Columbia, MO, 65211, USA. Lin-Quan Ge and Ting Xia contributed equally to this work. Correspondence and requests for materials should be addressed to L.-Q.G. (email: lqge1027@163.com) or J.-C.W. (email: jincaiwu1952@sina.com)
Adult males emerged from the 3rd instar nymphs fed with dietary dsPHF7 significantly decreased body weight and contents of soluble MAG protein and arginine at 2 DPE (F = 46.6, df = 2, 14, P = 0.0001 for body weight; F = 25.6, df = 2, 26, P = 0.001 for soluble MAG protein; F = 57.0, df = 2, 14, P = 0.0001 for arginine content) (Fig. 3). Dietary dsPHF7 treatment in nymphs led to significantly reduced adult male body weight, down by 15% (from 8.3 mg to 7.1 mg) compared to untreated controls and by 13% (from 8.2 mg to 7.1 mg) relative to dsGFP controls (Fig. 3A). We also recorded reduction of soluble MAG protein content in treated males, down by 17% (from 12.8 mg/g to 10.6 mg/g) compared to untreated controls and by 35% (from 28.7 ng/L to 18.6 ng/L) relative to dsGFP controls (Fig. 3C). However, no significant impact on adult male longevity (F = 1.5, df = 2, 68, P = 0.23) was recorded (Fig. 3D).

Here we designed experiments to test our hypothesis that a single male gene product, NIPH7, influences parameters of female reproductive biology via mating. If this idea is supported by experimental results, the gene encoding NIPH7 could potentially serve as a target for RNAi based control of BPH in transgenic plants.

Figure 1. The influence of dietary dsNIPH7 on expression of the target gene during 1, 3, 5 and 7 days following adult male emergence. NIPH7 expression value of untreated males was converted to 1. The histogram bars show mean relative gene expression (n = three independent biological replicates) and the error bars represent standard deviation (t-test, P < 0.05). Gene expression was normalized using actin-1 as reference gene.

Influence of dietary dsNIPH7 on adult males. Adult males emerged from the 3rd instar nymphs fed with dietary dsNIPH7 significantly decreased body weight and contents of soluble MAG protein and arginine at 2 DPE (F = 46.6, df = 2, 14, P = 0.0001 for body weight; F = 25.6, df = 2, 26, P = 0.001 for soluble MAG protein; F = 57.0, df = 2, 14, P = 0.0001 for arginine content) (Fig. 3). Dietary dsNIPH7 treatment in nymphs led to significantly reduced adult male body weight, down by 15% (from 8.3 mg to 7.1 mg) compared to untreated controls and by 13% (from 8.2 mg to 7.1 mg) relative to dsGFP controls (Fig. 3A). We also recorded reduction of soluble MAG protein content in treated males, down by 17% (from 12.8 mg/g to 10.6 mg/g) compared to untreated controls and by 14% (from 12.4 mg/g to 10.6 mg/g) compared to dsGFP controls (Fig. 3B). Dietary dsNIPH7 treatment in nymphs reduced arginine content in the resulting adult males, down by 38% (from 29.8 ng/L to 18.6 ng/L) compared to untreated controls and by 35% (from 28.7 ng/L to 18.6 ng/L) relative to dsGFP controls (Fig. 3C). However, no significant impact on adult male longevity (F = 1.5, df = 2, 68, P = 0.23) was recorded (Fig. 3D).

Tissue-specific expression of the NIPH7 gene. To investigate the tissue-specific expression of NIPH7, total RNA was isolated from male heads (MH), male thoraxes (MT), male fat bodies (MBF), male internal reproductive organ (MIRO), female heads (FH), female thoraxes (FT), female fat bodies (FFB) and female internal reproductive organ (FIRO) for qPCR analysis. Expression values of NIPH7 in MIRO, MIRO, and FFB were significantly higher when compared with that in MH, increasing by 2.7,-, 10.7-, and 1.9-fold at 2 DPE, respectively, while no significant differences in NIPH7 levels between MFB and FFB tissues were observed (Fig. 2). However, NIPH7 was barely expressed in FIRO (Fig. 2).

Result
Dietary dsNIPH7 reduces gene expression. Figure 1 showed that NIPH7 expression level in the adult males emerged from the 3rd instar nymphs fed with dietary dsNIPH7 was significantly down-regulated from 1, 3, 5 and 7 post-emergence (DPE) (F = 186.1, df = 2, 24, P = 0.0001). Dietary dsNIPH7 treatments led to reduced NIPH7 expression in males, approximately by 44 ~ 60% compared to untreated control, and by 48% ~ 65% compared to dsGFP control at 1, 3, 5 and 7 DPE, respectively. However, no significant differences on the average of NIPH7 expression levels in the dsRNA-treated adult males between 1, 3, 5, and 7 DPE were observed (F = 1.1, df = 3, 24, P = 0.40) (Fig. 1). In addition, no remarkable interaction effects existed between DPE and dsRNA treatments in terms of the average expression levels of NIPH7 (F = 1.4, df = 6, 24, P = 0.25).

which expresses in a wide range of tissues, particularly in the testis with a high expression level. It may play an important role in stimulating transcription involved in testicular development and/or spermatogenesis. PHF7 is an important factor for male germline sexual identification in Drosophila, and PHF7 exhibits male-specific expression in early germ cells, germline stem cells and spermatogonia. The PHD finger protein has been found in many regulatory proteins from plants to animals, which is frequently associated with chromatin to mediate transcriptional regulation. In a similar vein, BPH treated with the organophosphate tsp increased the expression of several proteins, including a spermatogenesis-associated protein like 5 (SPATA5) and testis development is an important factor for male germline sexual identification in Drosophila.
females (F) body weight in females, down by 21% (from 24.0 mg/g to 18.9 mg/g) compared to untreated control males mated with the control females and by 20% (from 23.8 mg/mg to 18.9 mg/g) compared to dsGFP control males mated with the control females (Fig. 4A). Suppression of NIPHF7 expression in males mated with the control females reduced soluble ovarian protein content in females, down by 47% (from 8.0 mg/g to 4.2 mg/g) compared to dsGFP controls males with the control females (Fig. 4C), but there was no impact of dsNIPHF7-treated males on longevity of adult females via mating ($F = 1.9$, $df = 2$, 68, $P = 0.15$) (Fig. 4D).

Control females mated with dsNIPHF7-treated males significantly decreased YPS abundance in fat bodies of adult females at 2 and 3 DPE ($F = 44.4$, $df = 2$, 14, $P = 0.0001$ for 2DPE (Fig. 4E); $F = 289.3$, $df = 2$, 14, $P = 0.0001$ for 3DPE (Fig. 4F), down by 30% (from 7.72 $\times$ 10^6/mL to 4.62 $\times$ 10^6/mL) and by 40% (from 2.72 $\times$ 10^6/mL to 2.10 $\times$ 10^6/mL) at 2 and 3 DPE, respectively, compared to untreated control males mated with the control females; by 38% (from 7.54 $\times$ 10^6/mL to 4.62 $\times$ 10^6/mL) and 24% (from 2.76 $\times$ 10^6/mL to 2.10 $\times$ 10^6/mL) at 2 and 3 DPE relative to dsGFP males mated with the control females, respectively.

Influence of dietary dsNIPHF7 treated males on reproduction of females via mating. Dietary dsNIPHF7-treated males mated with the control female significantly decreased the number of eggs laid by adult females ($F = 13.9$, $df = 2$, 68, $P = 0.0001$), down by 40% (from 443 to 262 eggs/female) compared to untreated control males mated with the control females and by 37% (from 419 to 262 eggs/female) compared to dsGFP control males mated with the control females (Fig. 5A). The pre-oviposition period refers to the interval, in days, between adult emergence and the onset of first egg-laying. The preoviposition period was not affected by dietary dsNIPHF7-treated males mated with the control females in adult females ($F = 0.5$, $df = 2$, 68, $P = 0.6$) (Fig. 5B). However, a shortened oviposition period was found in adult females ($F = 5.9$, $df = 2$, 68, $P = 0.004$), down by 21% (from 29.1 days to 22.9 days) compared to untreated control males mated with the control females and by 18% (from 28.0 days to 22.9 days) compared to dsGFP control males mated with the control females (Fig. 5C).

Dietary dsNIPHF7-treated males led to malformed internal reproductive organ. The external morphology of ovaries prepared from females (control-♀) mated with experimental males (dsNIPHF7-♂ or dsGFP-♂), was also influenced by dietary dsRNA construct. Observation reveals that the ovarioles in the control females mated with untreated males (Fig. 6A) or with dsGFP-treated males (Fig. 6B), had one or two fully developed banana-shaped oocytes at 2DPE. However, control females mated with males exposed to dietary dsNIPHF7 during the nymph stage resulted in undeveloped ovaries and severely inhibited oocyte growth in the ovaries (Fig. 6C). No fully developed oocytes were observed at 2DPE in the dsNIPHF7-treated group (Fig. 6C).

Compared to untreated males (Fig. 6D) and dsGFP-treated males (Fig. 6E), dietary dsNIPHF7 treatment led to significant malformation of vas deferens, seminal vesicle, and influenced testis development in males internal reproductive organ (MIRO) at 2 DPE (Fig. 6F), but no externally visible effect on paragonia glands was observed (Fig. 6F).
Dietary dsNlPHF7-treated males led to reduced Nlvg mRNA expression via mating. We examined the expression level of Nlvg mRNA in the control females mated with dsNlPHF7-treated and dsGFP-treated males (Fig. 7). The control females mated with males exposed to dietary dsNlPHF7 or dsGFP led to significantly down-regulated Nlvg expression at 2 DPE ($F = 53.9$, df = 2, 8, $P = 0.0001$), down by 55% compared to the control females mated with untreated males group and by 57% compared to the control females mated with dsGFP-treated males at 2DPE (Fig. 7A). We also recorded similar reduction in Nlvg expression at 3 DPE ($F = 66.2$, df = 2, 8, $P = 0.0001$), down by 51% compared to the control females mated with untreated males and by 52% compared to the control females mated with dsGFP-treated males at 3 DPE (Fig. 7B).

Dietary dsNlPHF7 treatments males led to reduced offspring and hatching rate. Table 1 showed that dietary dsNlPHF7 significantly reduced the number of offspring and hatching rate when the control females mated with dsNlPHF7-treated males ($F = 31.1$, df = 3, 19, $P = 0.0001$ for number of offspring; $F = 36.1$, df = 3, 19, $P = 0.0001$ for hatching rate) (Table 1). The dietary dsNlPHF7-treated males mated with the control females led to reduced number of offspring, down by 66% (from 422 to 143) compared to untreated control males mated with the control females and by 67% (from 438 to 143) relative to dsGFP-treated males mated with the control females.
Figure 4. Influence of dietary dsNPHF7 of adult males on adult females via mating. Panel (A): The histogram bars show mean body weight (n = five independent biological replicates (10 males/replicate). Panel (B): Mean soluble ovarian protein content ± SE (mg/g) at 2 DPE. Panel (C): Mean soluble fat body protein content ± SE (mg/g) at 2 DPE. Panel (D): The histogram bars show mean longevity ± SE (n = 23 independent biological replicates). Panels (E and F): the histogram bars show mean numbers ± SE of YLS at 2 DPE and 3 DPE. Histogram bars annotated with the same letter are not significantly different (t-test, p < 0.05).
Similarly, the control females mated with dsNlPHF7-treated males reduced egg hatching rate, down by 18% (from 0.93 to 0.76) compared to untreated control males mated with the control females and by 19% (from 0.94 to 0.76) relative to dsGFP-treated males mated with the control females. However, the dietary dsNlPHF7 treatments did not influence gender ratio of offspring (Table 1).

**Discussion**

The data reported in this paper strongly support our hypothesis that suppressing *NlPHF7* expression in males influences the reproductive physiology of female partners via mating, which reduces BPH population growth in agroecosystems. Our data show the following five conclusions: 1) *NlPHF7* was highly expressed in MFB, MIRO and FFB tissues at 2 DPE; 2) dietary dsNlPHF7 treatments reduced *NlPHF7* expression, body weight, soluble MAG protein contents, arginine contents, and malformed IRO in males; 3) similar treatments with experimental males reduced numbers of YLS, ovarian development, soluble ovarian protein contents and soluble fat body protein contents in their untreated female mating partners; 4) dietary dsNlPHF7 treatments in males altered female reproductive biology, including shortened oviposition periods and reduced *Nlvg* expression and egg laying; 5) Suppression of *NlPHF7* level reduced the number of offspring and egg hatching rate. However, the treatments did not influence adult longevity and previposition periods. Taken together, these data indicate that suppressing expression of *NlPHF7* in males strongly altered some, but not all, aspects of female reproductive biology. The significance of this finding lies in a direct demonstration of the influence of a single male-derived protein on female partners via mating.

Spermatogenesis is a highly regulated complex process, involving both intrinsic and extrinsic regulators, as well as interaction between germ cells and sertoli cells\(^{15}\). The intrinsic regulation of gene expression...
in spermatogenesis occurs at three phases: transcription, translation and post-translation. Spermatogenesis is further subjected to secondary regulation by endocrine, paracrine, and autocrine signals transmitted indirectly through surrounding somatic cells including Sertoli cell\(\text{16}\). Defective spermatogenesis may result from systemic disease, malnutrition, endocrinological disorders, genetic defects, anatomical obstruction, infections, and environmental toxins\(\text{17}\). NYD-SP6 (PHF7) might activate transcription through PHD zinc finger, regulating potential protein likely responsible for cell proliferation including germ cell development\(\text{11}\). Many nuclear transcription

Figure 6. Dietary ds\(\text{NIPHF7}\) led to malformed reproductive systems at 2 DPE. The third instar nymphs were treated with dietary ds\(\text{NIPHF7}\). Panels (A–C): Reproductive tracts were isolated from females and photographed using an OLYMPUS SZX16 microscope. The reduced sizes of ovaries were noticed. Panels (D–F): Reproductive tracts were isolated from males and photographed using an OLYMPUS SZX16 microscope. The reduced sizes of the vas deferens, testis, and seminal vesicle were observed.

Figure 7. Control females mated with the dietary ds\(\text{NIPHF7}\) males led to decreased \(\text{Nlg}\) mRNA expression at 2 DPE (A) and 3 DPE (B). Values were normalized relative to the reference gene, actin-1. Histogram bars represent the mean values \(\pm\) SE (\(n=\) three replicates). Histogram bars annotated with the same letter are not significantly different (t-test, \(p<0.05\)).
factors, which are important for germ cell development, have been reported to contain PHD finger domain, which is localized in nucleus and implicated in transcriptional regulation.36, 37. NIPHF7 is expressed throughout the first seven days of male adulthood, allowing the protein to sexually transfer to females during each mating. The current results showed that dietary dsNlPHF7 treatment resulted in malformation of vas deferens, seminal vesicle, and retardation of testis growth in M. RO at 2 DPE. We speculate that knockdown NIPHF7 influences spermatogenesis transcription phases, and also might further influence cognate gene expression in spermatogenesis, which influences male spermatogenesis phases. In adult males of Ephesia cautella, a greater size or a heavier weight has been used as an indicator of "good quality", regarded as a possession of optimal genes and a larger sperm supply.38, 39. Males that mate with heavy or average-sized C. jactata females may sire more offspring, which have a higher rate of survival.40. Our current results showed that dietary dsNlPHF7 treatment resulted not only in malformation of vas deferens, seminal vesicle, and retardation of testis growth at M. RO, but also decreased male body weight and female body weight, and reduced number of offspring and hatching rate of eggs via mating. Therefore, our findings imply that NIPHF7 plays an important role in BPH reproduction and population growth.

PHF7 is expressed in both males and females of D. melanogaster, with a predominant expression in M. RO. Loss-of-function of PHF7 mutation affected spermatogenesis, but not oogenesis in D. melanogaster, indicating that the PHF7 gene is important for fertility in males but not in females.41. Therefore, PHF7 is called the male reproductive gene. Silencing NIPHF7 might reduce the expression of cognate gene and inhibit the development of vas deferens, seminal vesicle, and testis, which accordingly led to reduced MAG proteins in males. It has been elucidated that the male paternity share of female's progeny are influenced by many factors such as nutrient status,42 male dominance,43 and MAG proteins.44 In D. melanogaster, MAG proteins mediate a variety of effects that benefit males, including the stimulation of female egg protection and receptivity reduction after mating.45, 46. Likewise, MAG protein with the treated males increase oviposition rate and sexual receptivity and decrease life span in female crickets.47 Many insect studies have also demonstrated that male accessory gland peptides regulate female reproductive performance via mating. For example, the adult male MAG proteins of D. melanogaster synthesize and secrete a peptide, thus stimulating oviposition.48. MAG proteins regulate spermatophore formation, egg maturation and oviposition in Heliothis virescens.49 Also, MAG proteins can influence reproductive behaviors such as remating, ovulation, and egg-laying.50, 51. Previous studies have demonstrated that insecticide treatments enhanced BPH male accessory gland (MAG) protein content.52, 53. Compared to copulation with untreated males, females mated with insecticide-treated males increased fecundity, registered as increased numbers of eggs laid.54. NIPHF7 gene expression level in tzp-treated male N. lugens was significantly higher than that of untreated control.55 Similarly recorded, dietary dsNlPHF7 treatment led to reduction of arginine content. Arginine, a necessary amino acid for sperm, is associated with spermatogenesis. Arginine is a precursor in the synthesis of nitric oxide (NO). NO promotes spermatogenesis and enhances sperm vigor and sperm insemination ability.56, 57. Therefore, we infer that dietary dsNlPHF7 might influence sperm motility, sperm counts, and spermatogenesis in adult males. Additionally, fewer MAG proteins or nutrition substances transferred to adult females via mating cause fewer eggs to be laid.

Surprisingly, NIPHF7 suppression in males by RNAi significantly influenced female reproductive biology, resulting in decreased protein content in fat bodies and ovaries and reduced number of egg-laid by adult females. Zeng et al.58 reported that egg production showed a positive correlation with vitellogenin content of fat body in Heliothis virescens. The reduced protein contents can disrupt BPH biology, including production of yolk proteins. Vitellogenins are produced in fat bodies and the reduced fat body protein contents may impose a limitation on the ability to produce vitellogenin, which can restrict ovarian development and reproduction. The relative expression of Nvng encoding Vg was reduced in females after mating with dsNlPHF7-treated males as shown in the present study. The previous results demonstrated that MAG protein of tzp-treated males was significantly increased compared to untreated control and JH III titer was increased as well, then stimulating female fecundity via mating.59, 60. Likewise, proteins in fat body and ovary of females mated with tzp-treated males were significantly increased compared to females mated with untreated males.61 The current data also showed that suppression of NIPHF7 reduced BPH population growth and hatching rate of eggs-laid. We infer that dietary dsNlPHF7-treated males might transfer fewer nutrition substances or hormonal substances to females via mating, resulting in decreased Vg expression and Vg synthesis as well as egg-laying in adult females.

Dietary dsNlPHF7 treatments led to reduced YLS abundance in adult females at 2 DPE and 3 DPE via mating. The previous investigation has shed light on a relationship between YLS and amino acid requirements in BPH.50, 51. The BPH requirements of essential amino acids were closely related to the abundance of YLS.62 Artificial reduction of the symbionts abundance delayed growth and decreased survival rate, adult emergence rate, body weight, and fecundity.63. Symbiotic bacteria in pea aphids also significantly affected amino acid metabolism.64. In terms

| Treatment | Number of offspring | Hatching rate | Gender ratio | PGI(N1/N0) |
|-----------|---------------------|---------------|--------------|------------|
| Control   | 422.8 ± 73.3a       | 0.93 ± 0.02a  | 1.90 ± 0.66a | 105.5      |
| dsGFP     | 438.8 ± 89.7a       | 0.94 ± 0.01a  | 1.91 ± 0.60a | 109.7      |
| dsNlPHF7  | 143.0 ± 16.7b       | 0.76 ± 0.05b  | 2.47 ± 0.19a | 35.8       |

Table 1. Influence of dietary dsNlPHF7-treated males mated with the control females on the number of offspring, hatching rate, and gender ratio. *Means ± SE of five replicates. Means within columns followed by different letters are significantly different at the 5% level (p < 0.05, PLSD test). Control group: control-♀ x dsNlPHF7-♂; dsGFP group: control-♀ x dsGFP-♂; dsNlPHF7 group: control-♀ x dsNlPHF7-♂.
of the physiological role, the YLS provides essential amino acids and possible proteins required for host embryo formation and post-embryonic development. The symbionts are essential to meet nutritional amino acid needs of hosts for production of a healthy complement of proteins. Therefore, we infer that suppression NlPHF7 expression in males might transfer fewer accessory gland proteins (including nutrition substances) to females via mating, and result in less symbiont maintenance in females, and influence female reproduction. In the present study, we found that YLS abundance of control females mated with dietary dsNlPHF7-treated males at 3 DPE was significantly lower than that in those mated with dsNlPHF7-treated males at 2 DPE. The number of symbiotic bacteria increased significantly with growth of nymphs, and the density of Wolbachia in the adult population of Guangxi N. lugens was greatly reduced with the increase of age, which is consistent with our previous experimental results. YLS abundance can be influenced by many factors, which supply insect energy and nutrition. Changes of fat and glycogen contents in fat body also affect the number of YLS in hosts. Temperature is the most important influence factor, and its interaction with host symbiosis has already been reported.

In summary, NlPHF7 in males plays an important role in regulating female fecundity, egg hatching rate, and population growth via mating. It exerts profound molecular and biochemical effects on production of Vg and likely other proteins, and these effects can be indirectly registered at the levels of organismal reproduction and BPH population dynamics. This study not only provides evolutionary insights into reproductive strategies, but also facilitates the development of novel means for controlling insect pests via identifying effective target genes in males.

### Materials and Methods

#### Rice variety and culture.

Rice (Oryza sativa L.) variety Ninjing 4 (japonica rice, commonly grown in Jiangsu province) was used in all experiments. Seeds were sown outdoors in cement tanks (height 60 cm, width 100 cm, and length 200 cm) containing standard rice-growing soil. When seedlings reached the six-leaf stage, they were transplanted into 16 cm diameter plastic pots containing four hills per pot, three plants per hill and used for experiments at the tillering stage.

#### Insect culture.

BPHs were obtained from a laboratory population maintained in a greenhouse under our standard conditions (26 ± 2 °C, with 70–80% humidity and a 16:8D photoperiod) at Yangzhou University. The insect colony was originally obtained from the China National Rice Research Institute (Hangzhou, China). Before the experiments started, the colony was allowed to reproduce for two generations in cement tanks (60 × 100 × 200 cm) under natural conditions in Yangzhou.

#### dsRNA synthesis.

We designed gene-specific dsNlPHF7 primers and amplified a 310-bp (388–707 bp) NlPHF7 cDNA fragment using forward and reverse primers containing the T7 primer sequence at the 5' ends (Table 2). The amplification program was 35 cycles of 95 °C for 40 s, 58 °C for 40 s and 72 °C for 1 min, with a final extension step of 72 °C for 10 min. The sequence was verified by sequencing (Invitrogen, Shanghai, China). We used the GPF gene (ACY56286; provided by Zhang Chuan-xi, Institute of Insect Sciences, Zhejiang University) as control dsRNA and amplified a 688 bp fragment using primers listed in Table 2. For NlPHF7 and the control GPF gene, we used the T7 Ribomax™ Express RNAi System (Promega, Sunnyvale, CA) for dsRNA synthesis, following the Promega instructions. We generated sense and antisense dsRNAs in separate 20 µL reaction volumes. The dsRNAs were annealed by mixing and incubating at 70 °C for 10 min, and then cooling to room temperature over 20 min. A 2 µL RNase A solution (4 mg/ml) and 2 µL RNase-free DNase (1 u/µL) were added to the reaction tube and incubated in a 37 °C water bath for 30 min. The dsRNA was precipitated by adding 110 µL 95% ethanol and 4 µL 3 M NaAc

---

We used the T7 Ribomax™ Express RNAi System (Promega, Sunnyvale, CA) for dsRNA synthesis, follow-
4.4 μL 3 M sodium acetate (pH 5.2), then washed with 0.5 mL 70% ethanol and dried at room temperature. The dried product was dissolved in 50 μL nuclease-free water. The purified dsRNAs were quantified by spectroscopy. To deliver dsRNA into BPH, nymphs were reared on an artificial diet amended with dsRNA 46, with some modifications to the rearing protocol. Previous results indicated that dsRNA feeding led to rapid and significant reduction in expression levels of BPH genes 47. We used glass cylinders (15.0 × 2.5 cm diameter) as feeding chambers, with four dsRNA concentrations, 0.125, 0.075, 0.05, and 0.025 μg/μL. The dsRNA solution (final concentration, 0.05 μg/μL) diet determined from the concentration response assay just mentioned, was used in all dsRNA assays. The artificial diet (20 g) was held between two layers of stretched Parafilm M membrane enclosed at the two open ends of the chamber (the diet capsule). The diet capsule was replaced every second day. The cylinders were covered with a piece of black cotton cloth, but the two ends with the artificial diet were exposed to light. Insects fed on the diets by puncturing the inner Parafilm M membrane of the diet capsule. Experimental insects were transferred into chambers and maintained on artificial diets for one day before initiation of the assays. Twenty 3rd instar individuals were transferred into each chamber, and three chambers were used to create three independent biological replicates. The rearing experiments were carried out in a humidified growth cabinet at 26 ± 2°C, 90% RH and a 16L:8D photoperiod. Mortality was recorded every other day.

**Influence of dietary dsRNA on biological performance parameters.** We determined the effects of dsNIPHF7 treatments on selected biological performance parameters. In preliminary experiments, we exposed second instar nymphs to the dsRNA construct, which led to over 95% mortality. Thereafter, we transferred 3rd instar nymphs to capsules containing dsRNA-laced diet. When the nymphs reached fifth (final) instar (about 8 days), they were collected, individually transferred into a glass jar (12 cm high × 10 cm), and reared on tillering rice plants under 26 ± 2°C, RH 90%, and 16L:8D. One newly emerged, untreated female (feeding artificial diet, control-♀) mated with one newly emerged dsRNA-treated male (dsNIPHF7-♂ or dsGFP-♂). We choose to assess many of the parameters at 2 DPE since the proteomic analysis of the *N. lugens* at 2 DPE showed that NIPHF7 was significantly increased 4. One hundred adult females and 100 adult males were collected separately at 2 days after mating. Fresh body weight, soluble ovary protein and soluble fat body protein content, contents of MAGs and arginine, and NIPHF7 expression level were determined. Then we individually paired a newly-emerged untreated female (feeding artificial diet, control-♀) with a dsRNA-treated male (dsNIPHF7-♂ or dsGFP-♂). Each pair (dsNIPHF7-♂ × Control-♀ or dsGFP-♂ × Control-♀ or Control-♂ × Control-♀) was maintained in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions (26 ± 2°C, RH 90%, and 16L:8D) for oviposition. Twenty-three copulating pairs were maintained to record duration of the pre-oviposition period, oviposition period, adult longevity, and fecundity for each pair. Rice stems were replaced daily during the pre-oviposition period, at two day intervals during the oviposition period and three day intervals during the female longevity period until the females died. The numbers of eggs laid on each rice stem were recorded under a light microscope. Fecundity of 23 mated pairs was evaluated by the average number of eggs laid.

**Protein Extraction and determinations.** Protein was extracted from fat bodies and ovaries using a method similar to Gong et al. 48. Individual adult females in all 15 females 2 days post-emergence (2 DPE) were dissected under a zoom stereomicroscope (model XTL20, Beijing Tech Instrument Co., Ltd., Beijing, China) in a cooled petri dish. Ovaries and fat bodies were removed and placed in separate, pre-weighed, ice-cold centrifuge tubes and then re-weighed using a Mettler-Toledo electronic balance (EC100 model; ±0.000 g sensitivity). A proportional amount of NaCl solution (0.4 M NaCl: 1 M PMSE, v:v at a ratio of 20 mL NaCl solution to 1 g ovary or fat body) was added to the tube, homogenized on ice, and centrifuged at 16,000 × g at 4°C for 20 min. The supernatant was collected after filtering the upper fat layer with glass fibers, placed at 4 °C overnight after adding ddH2O (1 supernatant: 10 ddH2O, v:v) and centrifuged again at 4 °C for 20 min. The protein sediment was dissolved with 1.5 ml pre-chilled 0.4 M NaCl solution after removing the supernatant. Protein from MAGs was extracted using the methods of Ge et al. 44. Individual adult males in all 10 males were dissected under a zoom-stereomicroscope in a cooled petri dish. MAGs were removed and placed in separate, pre-weighed, ice-cold Eppendorf tubes. To each tube, 600 μL of mixed solution (methanol/distilled water/acetic acid/methyl thioethanol; 80:18:2:0.1, v:v:v:v) was added. The contents were homogenized on ice and centrifuged at 12,000 × g at 4°C for 10 min. The upper fat layer was removed to yield the supernatant. Four hundred μL of mixed solution was added to the sediment in the tube, which was then centrifuged again and the supernatant collected.

We followed Bradford 49 to measure protein content using Coomassie Brilliant Blue R250 (Shanghai Chemical Agent Co., Ltd., Shanghai, China). A standard curve was established based on a BSA standard protein (Shanghai Biochemistry Research Institute, Shanghai, China). The absorbance at 595 nm was determined in a UV755 B spectrometer (Shanghai Precision Instrument Co., Ltd., Shanghai, China). The protein content in the sample solution was calculated according to the standard curve. Protein determinations were repeated nine times, with nine independent biological samples.

**Determination of arginine content.** We followed the instruction from an insect arginine ELISA kit (Qiaodu biological technology Co., LTD, Shanghai, China) to measure arginine content in insect tissues using the double antibody sandwich ELISA assay. Each treatment and control group (including 10 males, respectively) 2 days post-emergence (2 DPE) were accurately weighed, 1 mL PBS (pH7.4) was added, then homogenized adequately by hands, centrifuged at 3,000 × g for 20 min. The supernatants were collected carefully and refrigerated at −20°C. A total of 10 standard wells on the coated ELISA plates were used for the assay. 100 μL of standard substances and 50 μL of the standard dilution were respectively added to the first and second well, shaking adequately. Then 100 μL was taken from the each well, 50 μL of dilution was added to the third and fourth well, blended thoroughly. Subsequently, 50 μL of mixtures from the third and fourth well was removed, and 50 μL of mixtures each from the two wells were taken to the fifth and sixth well, mixed with 50μl of standard dilution,
Population growth. A population growth experiment was conducted using the method described by Bao et al.\textsuperscript{32} and Ge et al.\textsuperscript{33}. The experiment set three treatments groups: (1) untreated males (control-\(\varsigma\)) \times untreated females (control-\(\varphi\)); (2) dsGFP males (dsGFP-\(\varphi\)) \times untreated females (control-\(\varphi\)); (3) dsNLPHF7 males (dsNLPHF7-\(\varphi\)) \times untreated females (control-\(\varphi\)). The experiment was arranged with a randomized complete block design with five replicates. Two pair of newly emerged \textit{N. lugens} were released to rice plants at the tillering stage covered with a nylon cylindrical cage (20 cm diameter \times 80 cm height; screen size: 80-mesh) in each pot. When neonates of the new generation were produced, each treatment group were checked every day and the neonates were counted, then transferred into new plastic plots with the same tillering stage rice plants covered with a nylon

Observation of the number of yeast-like symbionts (YLS) in fat bodies. The procedure described in Noda\textsuperscript{30} was followed to measure the number of YLS of fat bodies with blood cell counter (0.01 mm, 1/400 mm\(^2\)) (25\textdegree 16 model, Shanghai Qijing Biochemical Reagent Co., Shanghai, China). We transferred the 3\textsuperscript{rd} instar nymphs to capsules containing dsRNA-laced diet; at their fifth (final) instar (8 days), nymphs were individually transferred into a glass jar (12 cm high \times 10 cm) and reared on rice plants at the tillering stage under 26 \pm 2 \degree C and 16L:8D. We paired individually paired a newly-emerged female (feeding artificial diet, \(\varphi\) control) with a dsRNA-treated male (dsNLPHF7-\(\varphi\) or dsGFP-\(\varphi\)). Each pair (dsNLPHF7-\(\varphi\) \times control-\(\varphi\) or dsGFP-\(\varphi\) \times control-\(\varphi\)) was maintained in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions (26 \pm 2 \degree C, RH 90\%, and 16L:8D) for observation of the number of YLS in fat bodies. Sixty uniform adult females were collected separately at 2 or 3 days after mating. This parameter was closely associated with insect energy and nutrition supply sites. We separately collected BPHs at 2 or 3 days after mating to evaluate the dynamic number of YLS in fat bodies at different DAE (day after emergence). Fat body was dissected from six adult females in treated (dsRNA-\(\varphi\)) or untreated females (control-\(\varphi\)) with a scalpel and dsGFP-\(\varphi\)) or untreated control (control-\(\varphi\) \times control-\(\varphi\)) group and homogenized gently in 200 \mu L saline solution (0.9\% NaCl). Homogenate (2 \mu L) was added to a blood cell counter (0.01 mm, 1/400 mm\(^2\)) and the numbers of YLS were counted under microscope using a 5 point sampling method. The numbers of YLS were counted from 80 squares (unit, mm\(^2\)) each time. Each treatment and control was replicated five times.

Body weights. Ten females or males were used as a replicate at 2 DPE. The insects were placed in pre-prepared centrifuge tubes and then weighed using a Mettler-Toledo electronic balance (EC100 model; \((1/10,000)\) g sensitivity). Each treatment and each control was replicated five times with five independent sets of insects.

qPCR analysis. We isolated total RNA from the five newly-emerged females, using a SV Total Isolation System Kit (model Z3100, Promega Corporation, Madison, WI, USA). First-strand cDNA was synthesized in a 10 \mu L reaction volume consisting of 0.5 \mu g of RNA, 0.5 \mu L of PrimeScript RT enzyme mix I, 0.5 \mu L of OligodT primer (50 \mu M), 2 \mu L of random hexamers (100 \mu M), 2 \mu L of PrimeScript Buffer (for real-time PCR) and RNase-free dH\textsubscript{2}O up to a final volume of 10 \mu L, following the PrimeScript RT Kit instructions (TaKaRa Biotechnology, Dalian, China). The cDNA was reverse transcribed using the following program: 37 \degree C for 15 min, 85 \degree C for 5 s and 4 \degree C for 5 min.

We similarly isolated total RNA from the dsRNA-treated and control adults (males or females). Portions (2 \mu L of the synthesized first-strand cDNA were amplified by qPCR in 20 \mu L reaction mixtures using a CFX96 real-time PCR system (Bio-Rad Co. Ltd., California, USA). We used two qPCR programs. For \textit{NlPHF7}, 94 \degree C for 2 min, followed by 40 cycles of 94 \degree C for 5 s, 60.4 \degree C for 30 s and 72 \degree C for 30 s. For \textit{Nlvitellogenin} (Nlvig), 94 \degree C for 2 min, followed by 40 cycles of 94 \degree C for 5 s, 59.7 \degree C for 30 s and 72 \degree C for 30 s. \textit{NlPHF7} (NLU003033) and \textit{Nlvig} (AB353856) mRNA levels were separately quantified in relation to the stable expression\textsuperscript{17} of constitutive actin-1 (EU179846). Primers used for qPCR analysis are listed in Table 2. After amplification, a melting curve analysis was performed in triplicate and the results were averaged. The values were calculated using three independent biological samples and the 2\textsuperscript{−ΔΔC\textsubscript{T}} method\textsuperscript{31} was used for the analysis of relative \textit{NlPHF7} expression level.

Population growth. A population growth experiment was conducted using the method described by Bao et al.\textsuperscript{32} and Ge et al.\textsuperscript{33}. The experiment set three treatments groups: (1) untreated males (control-\(\varphi\)) \times untreated females (control-\(\varphi\)); (2) dsGFP males (dsGFP-\(\varphi\)) \times untreated females (control-\(\varphi\)); (3) dsNLPHF7 males (dsNLPHF7-\(\varphi\)) \times untreated females (control-\(\varphi\)). The experiment was arranged with a randomized complete block design with five replicates. Two pair of newly emerged \textit{N. lugens} were released to rice plants at the tillering stage covered with a nylon cylindrical cage (20 cm diameter \times 80 cm height; screen size: 80-mesh) in each pot. When neonates of the new generation were produced, each treatment group were checked every day and the neonates were counted, then transferred into new plastic plots with the same tillering stage rice plants covered with a nylon
cylindrical cage (20 cm diameter × 80 cm height; screen size: 80-mesh) until the original female died. Neonates in the new plastic plot were checked every 2 day until adult emergence, recorded number of females and males, respectively. All adults of next generation were counted (all females plus all males). The rice shoots on which the adults had been feeding were then inspected thoroughly, and the numbers of unhatched eggs were recorded. Hatching rate was also recorded (all adults/all adults plus unhatched eggs). The population growth index (PGI) was expressed by the ratio of N1/N0, which was calculated by dividing the total number (N1) of adults of next generation by the number of adults released (N0 = 4).

Statistical analysis. Before performing an analysis of variance (ANOVA), data were evaluated for normality and homogeneity of variance using a Bartlett test. Based on these assessments, no transformations were needed. The results presented in figures are expressed as the means ± S.E. Two-way (days post-emergence and dsRNA treatment) ANOVAs were performed to analyze data in Fig. 1. One-way ANOVAs were performed to analyze all other data except for Fig. 1. Multiple comparisons of the means were conducted using Fisher’s Protected Significant Difference (PLSD) test. All analysis were conducted using the data processing system (DPS) of Tang and Feng 44.
