(Dated: March 31, 2022)

We describe a practical implementation of a (semi-deterministic) photon gun based on stimulated Raman adiabatic passage pumping and the strong enhancement of the photonic density of states in a photonic band-gap material. We show that this device allows deterministic and unidirectional production of single photons with a high repetition rate of the order of 100kHz. We also discuss specific 3D photonic microstructure architectures in which our model can be realized and the feasibility of implementing such a device using Er3+ ions that produce single photons at the telecommunication wavelength of 1.55µm.

PACS numbers: 42.70.Qs, 42.50.Dv, 03.67.Dd

In recent years, quantum optical information processing has attracted much attention, mostly for its applications to secure communication protocols [1] and the possibility of solving efficiently computational tasks that are impossible to solve on a classical computer [2]. Exploiting true single-photon sources — rather than coherent pulses is a goal of eavesdropper-proof quantum cryptography [3]. High-fidelity single-photon sources are also a requirement for scalable linear optical quantum computing [4].

Present-day research considers photon emission from single atoms or molecules (either in cavity QED [5, 6] or emission from color centers [7]) quantum dot structures [8], mesoscopic p-n diode structures [9], chemical compounds [10], or micro-pillars [11]. Spontaneous parametric down-conversion, on the other hand, may be used as a pseudo-single-photon source, conditioned upon detection of one photon out of the pair [12]. In the present proposal, we focus on the possibility of modifying spontaneous emission by placing the radiation source inside a 3D dielectric microstructure. It is known that the rate of spontaneous decay of an excited atom or ion can be tailored by the Purcell effect, whereby a cavity alters the density of modes of the vacuum radiation field, which in turn can lead to enhancement or inhibition of spontaneous decay of an atom inside the cavity [13].

Photonic crystals are periodically ordered dielectric materials that allow a very precise control of the flow of light and of the light-matter interaction. In this paper, we make use of a photonic crystal structures exhibiting a photonic band gap (PBG) [14]. In particular, we focus on a simplified 1D model of a complex 3D hetero-structure introduced in [15]. In the context of single photon devices, PBG materials provide the possibility of unidirectional enhancement of the atomic emission. As shown in Fig. 1, a 1D photonic crystal model can be physically realized in a waveguide channel in a 2D photonic crystal that is embedded in a 3D PBG material. The electromagnetic field is confined vertically by the PBG of the 3D structure (here, for example, we consider a woodpile crystal [17]) and in-plane by the stop gap of the 2D photonic crystal (a square lattice in this case) [16]. By tuning the characteristics of the microstructure (geometry and index of refraction contrast) [18], the linear defect in the 3D PBG can support a single waveguide mode, which experiences a sharp cutoff in the gap of 3D photonic crystal as shown in Fig. 2. In this case, the subgap generated by the waveguide channel has a true one-dimensional character, since there is only one direction available for wave propagation. The sharp cutoff of the guided mode at the Brillouin zone boundary gives rise to a low-group velocity (dω/dk → 0), which combined with the one-dimensional character of the system generates a divergent density of states (DOS) (ρ(ω) ∝ dk/dω → ∞). For an infinite structure, there is a physical square-root singularity in the photonic density of states (DOS) near the cutoff of the waveguide modes [19]. For a finite structure, the divergence is removed by the finite-size effects [19]. However, the strong variation with frequency of the photonic DOS remains [19]. Therefore, while we limit the present analysis to an idealized 1D photonic crystal in which the single-mode waveguide channel is modeled as an effective 1D photonic crystal consisting of alternating double-layer of quarter wave plates, we emphasize that this model can be implemented in carefully designed 3D dielectric hetero-structures (the electromagnetic field in the guided mode encounters a periodic 1D effective variation of the dielectric constant as it propagates along the waveguide channel). The most relevant features of the photonic crystals for realization of single photon “gun” devices (the rapid variation with frequency of the DOS and the unidirectional operation) are easily recaptured in the simplified 1D model. Essentially, for an N = 29 period stack with an index of refraction contrast of 2:1, the spontaneous decay rate at the band edge frequency is enhanced by a factor of 115 compared to...
FIG. 1: Photonic band-gap waveguide architecture for single-photon generation. The micro-structure consists of a waveguide channel in a 2D photonic crystal, which is embedded in a 3D photonic crystal. In this example, the 2D photonic guide channel in a 2D photonic crystal, which is embedded in photon generation. The micro-structure consists of a waveguide similar to one presented in Fig. 1 for propagation along the waveguide direction. The 3D photonic crystal is assumed to be a woodpile structure that presents a photonic band gap of about 18% of the mid-gap frequency. The linear waveguide is generated by removing one row of rods in the longitudinal direction. The 3D photonic crystal is assumed to be a woodpile structure that presents a photonic band gap of about 18% of the mid-gap frequency. The width and the height of the stacking rods in the woodpile structure are assumed to be a woodpile structure that presents a photonic band gap of about 18% of the mid-gap frequency. The width and the height of the stacking rods in the woodpile structure are assumed to be a woodpile structure that presents a photonic band gap of about 18% of the mid-gap frequency.

The density of modes at band-edge resonance is the dielectric constant of the embedding 3D photonic crystal. The ion could be placed with an atomic-force microscope or by sparse ion implantation midway during the structure’s growth. The wavelength of 1.55 μm of its $^{4}I_{13/2} \rightarrow ^{4}I_{15/2}$ transition ($|2\rangle \rightarrow |1\rangle$, for short) is most convenient for quantum communication with optical fibers. Excitation can be performed by pumping at 980 nm, corresponding to the $^{4}I_{11/2} \rightarrow ^{4}I_{15/2}$ transition ($|3\rangle \rightarrow |1\rangle$), see Fig. 3. However, even a 100% efficient population transfer to the upper state $|3\rangle$ does not guarantee that it will decay down to the state $|2\rangle$. For example, the level $^{4}I_{11/2}$ decays to $^{4}I_{15/2}$ about six times faster than to the level $^{4}I_{13/2}$. Instead, in-band pumping at 1480 nm may be used. Nevertheless, due to the relatively small radiative decay rate of the $|2\rangle \rightarrow |1\rangle$ transition, in-band pumping is not very efficient and, more importantly, does not have a deterministic character.

A more efficient and deterministic preparation of the emission-ready state $|2\rangle$ of the Er$^{3+}$ ion can be carried out by using stimulated Raman adiabatic passage (STIRAP) from the ground state $|1\rangle$. This method allows, in principle, for a 100% population transfer even for a strongly decaying intermediate state $|3\rangle$. A deterministic population transfer is achieved by first turning on the $\Omega_{23}$, and then turning on the $\Omega_{13}$ while $\Omega_{23}$ is turned off, all done adiabatically. Here $\Omega_{ij}$ denotes the Rabi frequencies of the STIRAP fields coupling the levels $|i\rangle$ and $|j\rangle$. If both pulses have the same Gaussian shape, the most efficient transfer is achieved when their peaks are separated by about $\tau$, and the adiabaticity condition $\tau \sqrt{\Omega_{13}^2 + \Omega_{23}^2} > 10$ is fulfilled. For atoms with dipole transitions in the IR optical range, the adiabaticity and optimization requirements are easily satisfied for relatively low-power, nanosecond pulses with nearly transform-limited spectral width.
ter the deterministic excitation process, the ion is left in its |2⟩ state for a time that is inversely proportional the spontaneous decay rate of the metastable state. Assume now we could arrange the properties of the dielectric micro-structure in such a way that the transition |2⟩ → |1⟩ frequency is placed in the spectral region surrounding the cutoff frequency of the waveguide mode. After the excitation process, the ion will feel a large density of modes and will decay very rapidly. This type of process we call “on demand” since the onset of spontaneous decay can be controlled externally. The process becomes more deterministic if the higher the local density of modes gets, that is, the sharper the band edge becomes. This increase in mode density can be achieved by increasing the longitudinal size (number of periods) of the photonic crystal.

We also note that photonic crystal heterostructure architecture in Fig. 1 has an additional advantage for practical implementations of a single-photon-gun device. By increasing the transverse size of the waveguide channel, the linear defect may support additional guided modes. These additional modes can be used to convey the external laser fields that drive the pumping process.

For concreteness, consider the model where-by the radiating ion is placed in the middle of an effective 29-layer dielectric structure with \( n_1 = 1 \) and \( n_2 = 2 \). The value of \( n_2 = 2 \) is somewhat arbitrary. The woodpile structure can be made out of very high index of refraction materials in an air matrix, such as Si or III-IV semiconductors, GaAs or InP etc. This means that we could use in our simulations a larger \( n_2 \) \( [n_2 \in (3.14, 3, 5)] \) index of refraction contrast. However, we employ an effective 1D model, and we expect the effective index of refraction to be somewhat lower than the actual index of refraction of the dielectric backbone. Suppose the ion is in the excited state |2⟩ and the transition frequency \( \omega_A \) corresponds to 0.781\( \omega_0 \) (here \( \omega_0 \) is the mid-gap frequency). Figure 3 shows the normalized spontaneous emission rate (with respect to the low frequency emission rate) that is proportional to the local DOS at the ion position (in this example, the ion is placed in the middle dielectric slab of the effective one dimensional photonic crystal). Note that due to the effective one-dimensional character of the device, the enhancement of the mode density preferentially occurs at a single mode of propagation. Correspondingly, the emission is highly directional along the waveguide channel and may be easily mode-matched to, say, a telecom fiber or other waveguide.

![FIG. 3: Schematic level diagram of Er\(^{3+}\) ion discussed in the context of the deterministic STIRAP pumping scheme. Using the technique of STIRAP, the population transfer to the level |3⟩ does not depend on the branching ratio and can be made with unit efficiency.](image)

We now consider the issues related to the speed of such a photon gun. The maximum repetition rate of that device is limited by the following factors: (1) the repetition rate of the ion excitation, and (2) the spontaneous decay rate (inverse lifetime) of the metastable ion state. For mode-locked laser diodes the repetition rate can be as high as 1 GHz, but is certainly in the 100 MHz range. That means that the limiting factor is the enhanced spontaneous decay rate of the erbium ion. Taking the lifetime of the excited ion to be 1 ms in the bulk \(12\), the enhanced spontaneous decay rate of the erbium ion can be of the order of 100 kHz, using the model above. But as mentioned earlier, this rate can be increased by sharpening the band edge with the addition of more periods or by increasing the index contrast. The increase of the mode density scales as \(N^2\), where \(N\) is the number of the periods. The total repetition rate of the device then can be as high as several MHz for realistic \(N\).

We also note that our single-photon device proposal eliminates the inverse relationship between the magnitude of the defect-mode DOS and the repetition rate of the device that would be present in a 3D PBG single defect-mode based proposal for a single photon gun (along the lines of Ref. \(24\)). In such a defect-mode de-
vice, the repetition rate is unfavorably limited by the cavity build-up time, which is inversely proportional to the quality factor of the defect mode, whereas the enhancement of the DOS is proportional to the the quality factor of the defect mode. Moreover, while the Purcell enhancement and emission narrowing effects in a 1D PBG structure rely crucially on preparing the emitting Er\(^{3+}\) dipole oriented parallel to the stack interfaces\(^{28}\), this is not the case for 3D PBG structures, where mode suppression and enhancement are omni-directional, independent of dipole orientation.

An alternative option for triggering the single photon emission process would be to make use of an intensity-dependent Kerr nonlinearity embedded in the dielectric backbone of the photonic crystal. If initially the ion frequency \(\omega_A\) falls inside the photonic band gap, the ion can not decay due to the lack of photonic modes. By applying an external optical or electric field (that induces a prescribed change of the refraction index of the nonlinear material and shifts the band gap to a different frequency interval), the ion transition frequency will now be located within the continuum of modes near the photonic band edge, and will suddenly feel a strong DOS and will spontaneously decay very rapidly. Our calculations show that for a dielectric structure consisting of 39 unit cells the required nonlinear relative change of the refraction index necessary to achieve single photon generation processes is \(\Delta n/n \approx 6 \times 10^{-3}\). Moreover, using the photonic crystal architecture presented in Fig. 1 we argue that the external laser field power required to achieve the necessary change in the index of refraction may be strongly reduced. By engineering the symmetry of the field distribution in the photonic crystal, one may achieve very strong field local enhancement at the nonlinear medium location, and, implicitly, a strong variation of the nonlinear index of refraction with only a fraction of the power that would have been required to obtain the same variation in the case of a homogeneous medium.

In summary, we have proposed a source of single photons switched by a STIRAP pumping process of a monatomic source placed in a light confining dielectric structure. The atomic source can be rapidly switched, at will, with a high repetition rate. The virtue of the mode confinement effect in the architecture presented in Fig. 1 is that the single photon gun device can be made small and compact. The unidirectional operation of the single photon device is achieved by tailoring the PBG geometry, while the repetition rate of the device is dramatically increased due to the strong enhancement of the optical DOS near a photonic band edge.
