Engineering Trustworthy Self-Adaptive Software with Dynamic Assurance Cases

Radu Calinescu, Simos Gerasimou, Ibrahim Habli, M. Usman Iftikhar, Tim Kelly, and Danny Weyns

Abstract—Building on concepts drawn from control theory, self-adaptive software handles environmental and internal uncertainties by dynamically adjusting its architecture and parameters in response to events such as workload changes and component failures. Self-adaptive software is increasingly expected to meet strict functional and non-functional requirements in applications from areas as diverse as manufacturing, healthcare and finance. To address this need, we introduce a methodology for the systematic ENgineering of TRUstworthy Self-adaptive Software (ENTRUST). ENTRUST uses a combination of (1) design-time and runtime modelling and verification, and (2) industry-adopted assurance processes to develop trustworthy self-adaptive software and assurance cases arguing the suitability of the software for its intended application. To evaluate the effectiveness of our methodology, we present a tool-supported instance of ENTRUST and its use to develop proof-of-concept self-adaptive software for embedded and service-based systems from the oceanic monitoring and e-finance domains, respectively. The experimental results show that ENTRUST can be used to engineer self-adaptive software systems in different application domains and to generate dynamic assurance cases for these systems.

Index Terms—Self-adaptive software systems, software engineering methodology, assurance evidence, assurance cases.

1 INTRODUCTION

Software systems are regularly used in applications characterised by uncertain environments, evolving requirements and unexpected failures. The correct operation of these applications depends on the ability of software to adapt to change, through the dynamic reconfiguration of its parameters or architecture. When events such as variations in workload, changes in the required throughput or component failures are observed, alternative adaptation options are analysed, and a suitable new software configuration may be selected and applied.

As software adaptation is often too complex or too costly to be performed by human operators, its automation has been the subject of intense research. Using concepts borrowed from the control of discrete-event systems [87], this research proposes the extension of software systems with closed-loop control. As shown in Fig. 1, the paradigm involves using an external software controller to monitor the system and to adapt its architecture or configuration after environmental and internal changes. Inspired by the autonomic computing manifesto [63], [69] and by pioneering work on self-adaptive software [67], [82], this research has been very successful. Over the past decade, numerous research projects proposed architectures [51], [72], [115] and frameworks [14], [41], [100], [114] for the engineering of self-adaptive systems. Extensive surveys of this research and its applications are available in [64], [85], [91].

In this paper, we are concerned with the use of self-adaptive software in systems with strict functional and non-functional requirements. A growing number of systems are expected to fit this description in the near future. Service-based telehealth systems are envisaged to use self-adaptation to cope with service failures and workload variations [14], [42], [111], avoiding harm to patients. Autonomous robots used in applications ranging from manufacturing [38], [54] to oceanic monitoring [18], [52] will need to rely on self-adaptive software for completing their missions safely and effectively, without damage to, or loss of, expensive equipment. Employing self-adaptive software in these applications is very challenging, as it requires assurances about the correct operation of the software in scenarios affected by uncertainty.

Assurance has become a major concern for self-adaptive software only recently [24], [28], [34], [35]. Accordingly, the research in the area is limited, and often confined to providing evidence that individual aspects of the self-adaptive software are correct (e.g. the software platform used to execute the controller, the controller functions, or the runtime adaptation decisions). However, such evidence is only one component of the established industry process for the assurance of software-based systems [10], [77], [102]. In real-world applications, assuring a software system requires the provision of an assurance case, which standards such as [103] define as

"a structured argument, supported by a body of evidence, that provides a compelling, comprehensible and
valid case that a system is safe for a given application in a given environment”.

Our work addresses this discrepancy between the state of practice and the current research on assurances for self-adaptive software. To this end, we introduce a generic methodology for the joint development of trustworthy self-adaptive software systems and their associated assurance cases. Our methodology for the ENgineering of TRUstworthy Self-adaptive softWare (ENTRUST) is underpinned by a combination of (1) design-time and runtime modelling and verification, and (2) an industry-adopted standard for the formalisation of assurance arguments [56], [94], [95].

ENTRUST uses design-time modelling, verification and synthesis of assurance evidence for the control aspects of a self-adaptive system that are engineered before the system is deployed. These design-time activities support the initial controller enactment and the generation of a partial assurance case for the self-adaptive system. The dynamic selection of a system configuration (i.e., architecture and parameters) during the initial deployment and after internal and environmental changes involves further modelling and verification, and the synthesis of the additional assurance evidence required to complete the assurance case. These activities are fully automated and carried out at runtime.

The ENTRUST methodology is not prescriptive about the modelling, verification and assurance evidence generation methods used in its design-time and runtime stages. This generality exploits the fact that the body of evidence underpinning an assurance case can combine verification evidence from activities including formal verification, testing and simulation. As such, our methodology is applicable to a broad range of application domains, software engineering paradigms and verification methods.

ENTRUST supports the systematic engineering and assurance of self-adaptive systems. In line with other research on self-adaptive systems (see e.g. [71], [113]), we assume that the controlled software system from Figure 1 already exists, and we focus on its enhancement with self-adaptation capabilities through the addition of a high-level monitor-analyse-plan-execute (MAPE) control loop. The components of the controlled software system may already support low-level, real-time adaptation to localised changes. For instance, the self-adaptive embedded system used as a running example in Section 3 is a controlled unmanned vehicle that employs built-in low-level control to maintain the speed selected by its high-level ENTRUST controller. Mature approaches from the areas of robust control of discrete-event systems (e.g. [75], [87], [88], [116]) and real-time systems (e.g. [73], [78]) already exist for the engineering of such low-level control, which is outside the scope of ENTRUST. Likewise, established assurance processes are available for the non-self-adaptive aspects of software systems (e.g. [9], [10], [59], [61], [90]). We do not duplicate this work. Using these processes to construct assurance arguments for the correct design, development and operation of the controlled software system, and for the derivation, validity, completeness and formalisation of the requirements from Fig. 1 is outside the scope of our paper. Thus, ENTRUST focuses on the correct engineering of the controller and on the correct operation of self-adaptive system, assuming that the controlled system and its requirements are both correct.

The main contributions of our paper are: 1) The first end-to-end methodology for (a) engineering self-adaptive software systems with assurance evidence for the controller platform, its functions and the adaptation decisions; and (b) devising assurance cases whose assurance arguments bring together this evidence. 2) A novel assurance argument pattern for self-adaptive systems, expressed in the Goal Structuring Notation (GSN) standard [56] that is widely used for assurance case development in industry [94]. 3) An instantiation of our methodology whose stages are supported by the established modelling and verification tools UP4AAL [6] and PRISM [75]. This methodology instance extends and integrates for the first time our previously separate strands of work on developing formally verified control loops [65], runtime probabilistic model checking [19] and dynamic safety cases [56].

These contributions are evaluated using two case studies with different characteristics and goals, and belonging to different application domains.

The remainder of the paper is organised as follows. In Section 2 we provide background information on assurance cases, GSN and assurance argument patterns. Section 3 introduces two proof-of-concept self-adaptive systems that we use to illustrate our methodology, which is described in Section 4, and to illustrate and evaluate its tool-supported instance, which is presented in Section 5. Section 6 presents our evaluation results, which show that the methodology can be used for the effective engineering of self-adaptive systems from different domains and for the generation of dynamic assurance cases for these systems. In Section 7 we overview the existing approaches to providing assurances for self-adaptive software systems, and we compare them to ENTRUST. Finally, Section 8 concludes the paper with a discussion and a summary of future work directions.

2 Preliminaries

This section provides background information on assurance cases, introducing the assurance-related terminology and concepts used in the rest of the paper. We start by defining assurance cases and their components in Section 2.1. Next, we introduce a commonly used notation for the specification of assurance cases in Section 2.2. Finally, we introduce the concept of an assurance argument pattern in Section 2.3.

2.1 Assurance Cases

An assurance case [1] is a report that supports a specific claim about the requirements of a system [9]. As an example, the assurance case in [81] provides documented assurance that the “implementation and operation of North European Functional Airspace Block (NEFAB) is acceptably safe according to ICAO, EC and EUROCONTROL safety requirements.” The documented assurance within an assurance case comprises (1) evidence and (2) structured arguments.

1. Assurance cases developed for safety-critical systems are also called safety cases. In this work, we are concerned with any self-adaptive software systems that must meet strict requirements, and therefore we talk about assurance cases and assurance arguments.
that link the evidence to the claim \[9\], possibly through intermediate claims.

Assurance cases are becoming mandatory for software systems used in safety-critical and mission-critical applications\[10,77,102\]. They are used in domains ranging from nuclear energy\[104\] and medical devices\[106\] to air traffic control\[43\] and defence\[103\]. A growing number of assurance cases from these and other domains are openly available (e.g.,\[81,105\]).

The development of assurance cases comprises processes carried out at all stages of the system life cycle\[102\]. Requirements analysis evidence and design evidence demonstrate that system reliability, safety, maintainability, etc. are considered in the early stages of the life cycle. Implementation, validation and verification evidence are then generated as the system is developed. Finally, evidence collected at runtime is used to update assurance cases during system maintenance.

As aptly described in\[102\], the assurance case must be “a living, cradle-to-grave document.” This is particularly true for self-adaptive software systems. For these systems, existing evidence needs to be continuously combined with new adaptation evidence, i.e., evidence that the system will continue to operate safely after self-adaptation activities.

### 2.2 Goal Structuring Notation

The assurance cases for self-adaptive systems introduced later in the paper are devised in the Goal Structuring Notation (GSN)\[65\], a community standard\[50\] widely used for assurance case development in industry\[94\]. The main GSN elements (Fig. 2) can be used to construct an argument by showing how an assurance claim (represented in GSN by a goal) is broken down into sub-claims (also represented by GSN goals), until eventually it can be supported by GSN solutions (i.e., assurance evidence from verification, testing, etc.). Strategies are used to partition the argument and describe the nature of the inference that exists between a goal and its supporting goal(s). The rationale (assumptions and justifications) for individual elements of the argument can be captured, along with the context (e.g., to describe the operational environment) in which the claims are stated.

In a GSN diagram, claims are linked to strategies, sub-claims and ultimately to solutions using ‘supported by’ connectives, which are rendered as lines with a solid arrowhead and declare inferential or evidential relationships. ‘Supported by’ connectives may be decorated with their multiplicity or marked as optional. The ‘in context of’ connective, rendered as a line with a hollow arrowhead, declares a contextual relationship between a goal or strategy on the one hand and a context, assumption or justification on the other hand.

Large or complex sections of the assurance argument can be organised into modules by means of GSN away goals referenced in the main argument and defined separately. Finally, GSN entities can be marked as uninstantiated to indicate that they are placeholders that need to be replaced with a concrete instantiation, and GSN goals can be marked as undeveloped to indicate that they need to be further developed into sub-goals, strategies and solutions.

As an example, Figure 3 shows a simple GSN assurance argument for the software part of a heating system. Its root goal (Goal 1) claims that the system is safe at all times. This claim is partitioned into sub-claims using a strategy (Strategy 1) that addresses the safety of the two system functions (i.e. control and monitoring) separately through sub-claims Goal 2 (for the control system) and Goal 2’ (for the monitor system), and includes sub-claim Goal 3 that the two functions are independent. The three sub-claims are supported by three solutions comprising assurance evidence from simulation, testing and formal proof, respectively.

### 2.3 Assurance Argument Patterns

To reduce the significant effort required to develop assurance cases, in our previous work on software assurance\[58\], we collaborated to the creation of a catalog of reusable GSN assurance argument patterns\[59\]. Each pattern considers the contribution made by the software to system hazards for a particular class of systems and scenarios. The GSN elements of a pattern that are generic to the entire class are fully developed and instantiated, whereas the entities that are specific to each system and scenario within the class are left undeveloped and/or uninstantiated.

As an example, Fig. 4 depicts an assurance argument pattern that is instantiated by the GSN assurance argument...
Goal 2: All system functions are independent
Goal 3: Interactions between system functions are non-hazardous
Goal 4: Argument based on addressing the safety of system functions
Context 2: (List of system functions)

FIG. 4. Example of a GSN assurance argument pattern

from Fig. 3. The elements surrounded by curly brackets ‘{‘ and ‘}’ in the pattern must be instantiated for each assurance argument based on the pattern, as further indicated by the triangular ‘uninstantiated’ symbol under the GSN entities that contain them. Goal 2 is marked with both this ‘uninstantiated’ symbol (because it contains elements in curly brackets) and a diamond-shaped ‘undeveloped’ symbol (because, like for the ‘choice’ sub-claims Goal 3 and Goal 4, additional GSN entities must be added underneath to complete the assurance argument); the two symbols are rendered overlapping under Goal 2.

In this paper, we devise a new assurance argument pattern, which is applicable to self-adaptive software systems.

3 SELF-ADAPTIVE SYSTEM EXAMPLES

This section introduces two examples of self-adaptive software systems that we will use to illustrate our the generic ENTRUST methodology in Section 4 and to illustrate and evaluate its tool-supported instantiation in Section 5.

3.1 Unmanned Underwater Vehicle (UUV) System

The first system is a self-adaptive UUV embedded system adapted from [52]. UUVs are increasingly used in a wide range of oceanographic and military tasks, including oceanic surveillance (e.g., to monitor pollution levels and ecosystems), underwater mapping and mine detection. Limitations due to their operating environment (e.g., impossibility to maintain UUV-operator communication during missions and unexpected changes) require that UUV systems are self-adaptive. These systems are often mission critical (e.g., when used for mine detection) or business critical (e.g., they carry expensive equipment that should not be lost).

The self-adaptive system we use consists of a UUV deployed to carry out a data gathering mission. The UUV is equipped with \(n \geq 1\) on-board sensors that can measure the same characteristic of the ocean environment (e.g., water current, salinity or temperature). When used, the sensors take measurements with different, variable rates \(r_1, r_2, \ldots, r_n\). The probability that each sensor produces measurements that are sufficiently accurate for the purpose of the mission depends on the UUV speed \(sp\), and is given by \(p_1, p_2, \ldots, p_n\). For each measurement taken, a different amount of energy is consumed, given by \(e_1, e_2, \ldots, e_n\). Finally, the \(n\) sensors can be switched on and off individually (e.g., to save battery power when not required), but these operations consume an amount of energy given by \(e_{\text{on}}^1, e_{\text{on}}^2, \ldots, e_{\text{on}}^n\) and \(e_{\text{off}}^1, e_{\text{off}}^2, \ldots, e_{\text{off}}^n\), respectively. The UUV must adapt to changes in the sensor measurement rates \(r_1, r_2, \ldots, r_n\) and to sensor failures by dynamically adjusting:

(a) the UUV speed \(sp\);
(b) the sensor configuration \(x_1, x_2, \ldots, x_n\) (where \(x_i = 1\) if the \(i\)-th sensor is on and \(x_i = 0\) otherwise).

In order to meet the quality-of-service requirements below:

R1 (throughput): The UUV should take at least 20 measurements of sufficient accuracy for every 10 metres of mission distance.

R2 (resource usage): The energy consumption of the sensors should not exceed 120 Joules per 10 surveyed metres.

R3 (cost): If requirements R1 and R2 are satisfied by multiple configurations, the UUV should use one of these configurations that minimises the cost function

\[
\text{cost} = w_1 E + w_2 sp^{-1},
\]

where \(E\) is the energy used by the sensors to survey a 10m mission distance, and \(w_1, w_2 > 0\) are weights that reflect the relative importance of carrying out the mission with reduced battery usage and completing the mission faster.

R4 (safety): If a configuration that meets requirements R1–R3 is not identified within 2 seconds after a sensor rate change, the UUV speed must be reduced to 0m/s. This ensures that the UUV does not advance more than the distance it can cover at its maximum speed within 2 seconds without taking appropriate measurements, and waits until the controller identifies a suitable configuration (e.g., after the UUV sensors recover) or new instructions are provided by a human operator.

3.2 Foreign Exchange Trading System

Our second system is a service-based system from the area of foreign exchange trading, taken from our recent work in [53]. This system, which we anonymise as FX for confidentiality reasons, is used by an European foreign exchange brokerage company. The FX system implements the workflow shown in Fig. 5 and described below.

An FX customer (called a trader) can use the system in two operation modes. In the expert mode, FX executes a loop that analyses market activity, identifies patterns that satisfy the trader’s objectives, and automatically carries out trades. Thus, the Market watch service extracts real-time exchange rates (bid/ask price) of selected currency pairs. This data is used by a Technical analysis service that evaluates the current trading conditions, predicts future price movement, and decides if the trader’s objectives are:

2. Cost (or utility) functions that employ weights to combine several performance, reliability, resource use and other quality attributes of software—accounting for differences in attribute value ranges and relative importance—are extensively used in self-adaptive software systems (e.g., [14, 41, 51, 91, 109]).
the self-adaptive FX system as described in Section 5.3.

 Nevertheless, our tool-supported instance of the ENTRUST methodology enabled the development of those specified by the requirements from our first case study (cf. Section 3.1). Nevertheless, our tool-supported instance of the ENTRUST methodology enabled the development of those specified by the requirements from our first case study (cf. Section 3.1).

 Note that requirements R1–R3 express two constraints and a qualitative change in service characteristics is signalled by the sensors of the self-adaptive FX system, the Order service invocation is bypassed, so that the FX system does not carry out any trade that might be based on incorrect or stale data. Note that requirements R1–R3 express two constraints and a qualitative change in service characteristics is signalled by the sensors of the self-adaptive FX system, the Order service invocation is bypassed, so that the FX system does not carry out any trade that might be based on incorrect or stale data.

 Fig. 5. Foreign exchange trading (FX) workflow

(i) “satisfied” (causing the invocation of an Order service to carry out a trade); (ii) “unsatisfied” (resulting in a new Market watch invocation); or (iii) “unsatisfied with high variance” (triggering an Alarm service invocation to notify the trader about discrepancies/opportunities not covered by the trading objectives). In the normal mode, FX assesses the economic outlook of a country using a Fundamental analysis service that collects, analyses and evaluates information such as news reports, economic data and political events, and provides an assessment on the country’s currency. If satisfied with this assessment, the trader can use the Order service to sell or buy currency, in which case a Notification service confirms the completion of the trade. We assume that the FX system has to dynamically select third-party implementations for each service from Fig. 5 in order to meet the following system requirements:

 R1 (reliability): Workflow executions must complete successfully with probability at least 0.9.

 R2 (response time): The total service response time per workflow execution must be at most 5s.

 R3 (cost): If requirements R1 and R2 are satisfied by multiple configurations, the FX system should use one of these configurations that minimises the cost function:

 \[ cost = w_1 \text{price} + w_2 \text{time}, \]

 where price and time represent the total price of the services invoked by a workflow execution and the response time for a workflow execution, respectively, and \( w_1, w_2 > 0 \) are weights that encode the desired trade-off between price and response time.

 R4 (safety): If a configuration that ensures requirements R1–R3 cannot be identified within 2s after a change in service characteristics is signalled by the sensors of the self-adaptive FX system, the Order service invocation is bypassed, so that the FX system does not carry out any trade that might be based on incorrect or stale data.

 Note that requirements R1–R3 express two constraints and an optimisation criterion that are qualitatively different from those specified by the requirements from our first case study (cf. Section 5.3). Nevertheless, our tool-supported instance of the ENTRUST methodology enabled the development of the self-adaptive FX system as described in Section 5.3.

 4 The ENTRUST Methodology

 The ENTRUST methodology supports the systematic engineering and assurance of self-adaptive systems based on monitor-analyse-plan-execute (MAPE) control loops. This is by far the most common type of control loop used to devise self-adaptive software systems [13], [34], [35], [41], [64], [74], [79], [91]. The engineering of self-adaptive systems based on essentially different control techniques, such as the control theoretical paradigm proposed in [47], is not supported by our methodology.

 ENTRUST comprises the tool-supported design-time stages and the automated runtime stages shown in Figure 6 and is underpinned by two key principles:

 1) Model-driven engineering is essential for developing trustworthy self-adaptive systems and their assurance cases. As emphasised in the previous section, model-based analysis, simulation, testing and formal verification—at design time and during reconfiguration—represent the main sources of assurance evidence for self-adaptive software. As such, both the design-time and the runtime stages of our methodology are model driven. Models of the structure and behaviour of the functional components, controller and environment are the basis for the engineering and assurance of ENTRUST self-adaptive systems.

 2) Reuse of application-independent software and assurance artefacts significantly reduces the effort and expertise required to develop trustworthy self-adaptive systems. Assembling an assurance case for a software system is a costly process that requires considerable effort and expertise. Therefore, the reuse of both software and assurance artefacts is essential for ENTRUST. In particular, the reuse of application-independent controller components and of templates for developing application-specific controller elements also enables the reuse of assurance evidence that these software artefacts are trustworthy.

 The ENTRUST stages and their exploitation of these two principles are described in the remainder of this section.

 4.1 Design-time ENTRUST Stages

 4.1.1 Stage 1: Development of Verifiable Models

 In ENTRUST, the engineering of a self-adaptive system with the architecture from Figure 7 starts with the development of models for:

 1) The controller of the self-adaptive system;

 2) The relevant aspects of the controlled software system and its environment.

 A combination of structural and behavioural models may be produced, depending on the evidence needed to assemble the assurance case for the self-adaptive system under development. ENTRUST is not prescriptive in this respect. However, we require that these models are verifiable, i.e., that they can be used in conjunction with methods such as model checking or simulation, to obtain evidence that the controller and the self-adaptive system meet their requirements. As an example, finite state transition models may be produced for the controllers of our UUV and FX systems from Section 5 allowing the use of model checking to verify that these controllers are deadlock free.
The verifiable models are application-specific. As illustrated in Figure 6, their development requires domain knowledge, which is based on a controlled system specification, and is informed by the system requirements. As in other areas of software engineering, we envisage that tool-supported methods will typically be used to obtain these models. However, their manual development or fully automated synthesis are not precluded by ENTRUST.

In line with the “reuse of artefacts” principle, ENTRUST exploits the fact that the controllers of self-adaptive systems implement the established MAPE workflow, and uses application-independent controller model template(s) to devise the controller model(s). These templates model the generic aspects of the MAPE workflow and contain placeholders for the application-specific elements of an ENTRUST controller.

Given the environmental and internal uncertainty that characterises self-adaptive systems, only incomplete system and environment models can be produced in this ENTRUST stage. These incomplete models may include unknown or estimated parameters, nondeterminism (i.e., alternative options whose likelihoods are unknown), parts that are missing, or some combination of all of these. For example, parametric Markov chains may be devised to model the controller and model checking to establish its correctness as in [38], [39].

**4.1.2 Stage 2: Verification of Controller Models**

The main role of the second ENTRUST stage is to produce controller assurance evidence, i.e., compelling evidence that a controller based on the controller model(s) from Stage 1 will satisfy a set of generic controller requirements. These are requirements that must be satisfied in any self-adaptive system (e.g., deadlock freeness) and are predefined in a format compatible with that of the controller model templates and with the method that will be used to verify the controller models. For example, if labelled transition systems are used to model the controller and model checking to establish its correctness as in [38], [39], these generic controller requirements can be predefined as temporal logic formulae.

The controller assurance evidence may additionally include evidence that some of the system requirements are satisfied. Thus, it may be possible to show that—despite the uncertainty characteristic to any self-adaptive system—application-specific fail-safe operating modes (e.g., those specified by requirements R4 of our UUV and FX systems from Section 3) are always reachable.

The assurance evidence generated in this stage of the methodology may be obtained using a range of methods that include formal verification, theorem proving and simulation. The methods that can be used depend on the types of models produced in the previous ENTRUST stage, and on the generic controller requirements and system requirements for which assurance is sought. The availability of tool support in the form of model checkers, theorem provers, SMT solvers, domain-specific simulators, etc. will influence the choice of these methods.

Preparing the design-time models, i.e., developing verifiable models and verifying the controller models, comes with a cost. However, by using tool-supported methods and exploiting reusable application-independent software, this cost can significantly be reduced and does not affect
the usability of ENTRUST compared to other related approaches. Related approaches that only provide a fraction of the assurances that ENTRUST achieves (as detailed when we discuss related work in Section 7) operate with design-time models that require a comparable effort to specify the models and provide the controller assurance evidence.

4.1.3 Stage 3: Partial Instantiation of Assurance Argument Pattern

This ENTRUST stage uses the controller assurance evidence from Stage 2 to support the partial instantiation of a generic assurance argument pattern for self-adaptive software. As explained in Section 2.3, this pattern is an incomplete assurance argument containing placeholders for the system-specific assurance evidence. A subset of the placeholders correspond to the controller assurance evidence obtained in Stage 2, and are therefore instantiated using this evidence. The result is a partial assurance argument, which still contains placeholders for the assurance evidence that cannot be obtained until the uncertainties associated with the self-adaptive system are resolved at runtime.

For example, the partial assurance argument for our UUV and FX systems should contain evidence that their controllers are deadlock free and that their fail-safe requirements R4 are always satisfied. These requirements can be verified at design time. In contrast, requirements R1–R3 for the two systems cannot be verified until runtime, when the controller acquires information about the measurement rates of the UUV sensors and the third-party services available for the FX operations, respectively. Assurance evidence that requirements R1–R3 are satisfied can only be obtained at runtime.

In addition to the two types of placeholders, the assurance argument pattern used as input for this stage includes assurance evidence that is application independent. In particular, it includes evidence about the correct operation of the verified controller platform, i.e. the software that implements application-independent controller functionality used to execute the ENTRUST controllers. This platform assurance evidence is reusable across self-adaptive systems.

4.1.4 Stage 4: Enactment of the Controller

This ENTRUST stage assembles the controller of the self-adaptive system. The process involves integrating the verified controller platform with the application-specific controller elements, and with the sensors and effectors that interface the controller with the controlled software system from Figure 1.

The application-specific controller elements must be devised from the verified controller models, by using a trusted model-driven engineering method. This can be done using model-to-text transformation, a method that employs a trusted model compiler to generate a low-level executable representation of the controller models. Alternatively, the ENTRUST verified controller platform may include a trusted virtual machine able to directly interpret and run the controller models. The second, model interpretation method has the advantage that it eliminates the need to generate controller code and to provide additional assurances for it.

4.1.5 Stage 5: Deployment of the Self-Adaptive System

In the last design-time stage, the integrated controller and controlled components of the self-adaptive system are installed, preconfigured and activated by means of an application-specific process. The pre-configuration is responsible for setting the deployment-specific parameters and architectural aspects of the system. For example, the pre-configuration of the UUV system from Section 3.1 involves selecting the initial speed and active sensor set for the UUV, whereas for the FX system from Section 3.2 it involves choosing initial third-party implementations for each FX service.

The deployed self-adaptive system will be fully configured and a complete assurance argument will be available only after the first execution of the MAPE control loop. This execution is typically triggered by the system activation, to ensure that the newly deployed self-adaptive system takes into account the current state of its environment as described next.

4.2 Runtime ENTRUST Stages

4.2.1 Stage 6: Self-adaptation

In this ENTRUST stage, the deployed self-adaptive system is dynamically adjusting its parameters and architecture in line with observed internal and environmental changes. To this end, the controller executes a typical MAPE loop that monitors the system and its environment, using the information obtained in this way to resolve the “unknowns” from the incomplete system and environment models. The resulting up-to-date system and environment models enable the MAPE loop to analyse the system compliance with its requirements after changes, and to plan and execute suitable reconfigurations if necessary.

Whenever the MAPE loop produces a reconfigured self-adaptive system, its analysis and planning steps generate adaptation assurance evidence confirming the correctness of the analysis results and of the reconfiguration plan devised on the basis of these results. This assurance evidence is a by-product of analysis and planning methods that may include runtime verification, simulation and runtime model checking. Irrespective of the methods that produce it, the adaptation assurance evidence is essential for the development of a complete assurance argument in the next ENTRUST stage.

4.2.2 Stage 7: Synthesis of Dynamic Assurance Argument

The final ENTRUST stage uses the adaptation correctness evidence produced by the MAPE loop to fill in the placeholders from the partial assurance argument, and to devise the complete assurance case for the reconfigured self-adaptive system. For example, runtime evidence that requirements R1–R3 of the UUV and FX systems from Section 3 are met will be used to complete the remaining placeholders from their partial assurance arguments. Thus, an ENTRUST assurance case is underpinned by a dynamic assurance argument that is updated after each reconfiguration of the system parameters and architecture. This assurance case captures both the full assurance argument and the
evidence that justifies the active configuration of the self-adaptive system.

The ENTRUST assurance case versions generated for every system reconfiguration have two key uses. First, they allow decision makers and auditors to understand and assess the present and past versions of the assurance case. Second, they allow human operators to endorse major reconfiguration plans in human-supervised self-adaptive systems. This type of self-adaptive systems is of particular interest in domains where human supervision represents an important risk mitigation factor or may be required by regulations. As an example, UK Civil Aviation Authority regulations [101] permit self-adaptation in certain functions (e.g., power management, flight management and collision avoidance) of unmanned aircraft of no more than 20 kg provided that the aircraft operates within the visual line of sight of a human operator.

5 Tool-Supported Instance of ENTRUST

This section presents an instance of ENTRUST in which the stages described in Section 3 are supported by the modelling and verification tools UPPAAL [6] and PRISM [75]. We start with an overview of this tool-supported ENTRUST instance in Section 5.1 followed by a description of each of its stages in Section 5.2. The UUV self-adaptive system introduced in Section 5.1 is used as a running example throughout these stage descriptions. We conclude with an end-to-end illustration of how the ENTRUST instance can be used to develop the FX self-adaptive system in Section 5.3.

5.1 Overview

The ENTRUST methodology can be used with different combinations of modelling, verification and controller enactment methods, which may employ different self-adaptive system architectures and types of assurance evidence. This section presents a tool-supported instance of ENTRUST that uses one such combination of methods. We developed this instance of the methodology with the aim to validate ENTRUST and to ease its adoption.

Our ENTRUST instance supports the engineering of self-adaptive systems with the architecture shown in Fig. 7. The reusable verified controller platform at the core of this architecture comprises:

1) A Trusted Virtual Machine that directly interprets and executes models of the four steps from the MAPE control loop (i.e., the ENTRUST controller models).
2) A Probabilistic Verification Engine that is used to verify stochastic models of the controlled system and its environment during the analysis step of the MAPE loop.

Using the Trusted Virtual Machine for controller model interpretation eliminates the need for a model-to-text transformation of the controller models into executable code, which is a complex, error-prone operation. Not having to devise this transformation and to provide assurance evidence for it are major benefits of our ENTRUST instance. Although we still need assurance evidence for the virtual machine, this was obtained when we developed and verified the virtual machine and is part of the reusable platform assurance evidence for the ENTRUST instance.

The Probabilistic Verification Engine consists of the verification libraries of the probabilistic model checker PRISM [75] and is used by the analysis step of the MAPE control loop. As such, our ENTRUST instance works with:

1) Stochastic finite state transition models of the controlled system and the environment, defined in the PRISM high-level modelling language. Incomplete versions of these models are devised in Stage 1 of ENTRUST, and have their unknowns resolved at runtime. All types of models that PRISM can analyse are supported, including discrete- and continuous-time Markov chains (DTMCs and CTMCs), Markov decision processes (MDPs) and probabilistic automata (PAs).
2) Runtime-assured system requirements expressed in the appropriate variant of probabilistic temporal logic, i.e., probabilistic computation tree logic (PCTL) for DTMCs, MDPs and PAs, and continuous stochastic logic (CSL) for CTMCs.

This makes our instantiation of the generic ENTRUST methodology applicable to self-adaptive systems whose non-functional (e.g., reliability, performance, resource usage and cost-related) requirements can be specified in the above

6. This assurance evidence is in the form of a comprehensive test suite and a report describing its successful execution by the virtual machine, both of which are available on our ENTRUST project website at https://www-users.cs.york.ac.uk/simos/ENTRUST/
logics, and whose behaviour related to these requirements can be described using stochastic models. As shown by the recent work of multiple research groups (e.g., [19], [26], [42], [45], [48], [86], [96]), this represents a broad and important class of self-adaptive software that includes a wide range of service-based systems, web applications, resource management systems, and embedded systems.

Also developed in Stage 1 of ENTRUST, the four controller models form an application-specific network of interacting timed automata [2], and are expressed in the modelling language of the UPPAAL verification tool suite [6].

Accordingly, UPPAAL is used in Stage 2 of ENTRUST to verify the compliance of the controller models with the generic controller requirements and with any system requirements that can be assured at design time. These requirements are defined in computation tree logic (CTL) [29].

In Stage 3 of our ENTRUST instance, a partial assurance argument is devised starting from an assurance argument pattern represented in goal structuring notation (GSN) [68]. GSN is a community standard [56] that is widely used for assurance case development in industry [94].

The controller enactment from Stage 4 involves integrating the timed-automata controller models with our verified controller platform.

In Stage 5 of ENTRUST, the controlled software system and its enacted controller are deployed, together with a Knowledge Repository that supports the operation of the controller. Initially, this repository contains: (i) the partial assurance argument from Stage 3; (ii) the system requirements to be assured at runtime; and (iii) the (incomplete) stochastic system and environment models from Stage 1.

During the execution of the MAPE loop in Stage 6 of ENTRUST, the Monitor obtains information about the system and its environment through Probes. This information is used to resolve the unknowns from the stochastic models of the controlled system and its environment. Examples of such unknowns include probabilities to ‘failure’ states for a DTMC, MDP or PA, rates of transition to ‘success’ states for a CTMC, and sets of states and transitions modelling certain system behaviours. After each update of the stochastic system and environment models, the Analyzer re-verifies the compliance of the self-adaptive system with its runtime-assured requirements. When the requirements are no longer met, the Analyzer uses the verification results to identify a new system configuration that restores this compliance, or to find out that such a configuration does not exist and to select a predefined failsafe configuration. The step-by-step actions needed to achieve the new configuration are then established by the Planner and implemented by the Executor through the Effectors of the controlled system.

Using the Probabilistic Verification Engine enables the Analyzer and Planner to produce assurance evidence justifying their selection of new configurations and of plans for transitioning the system to these configurations, respectively. This adaptation assurance evidence is used to synthesise a fully-fledged, dynamic GSN assurance argument in Stage 7 of our ENTRUST instance. As indicated in Figure 7, versions of the adaptation assurance evidence and of the dynamic assurance argument justifying each reconfiguration of the self-adaptive system are stored in the Knowledge Repository.

The implementation of the ENTRUST stages in our tool-supported instance of the methodology is summarised in Table 1 and described in further detail in Section 5.2. The UUV system introduced in Section 5.1 is used to support this description.

### 5.2 Stage Descriptions

#### 5.2.1 Development of Verifiable Models

**Controller models.** We devised two types of templates for the four controller models from Fig. 7: (i) *event triggered*, in which the monitor automaton is activated by a sensor-generated signal indicating a change in the managed system or the environment; and (ii) *time triggered*, in which the monitor is activated periodically by an internal clock. The event-triggered automaton templates are shown in Fig. 8 using the following font and text style conventions:

- **Sans-serif font** is used to annotate states with the atomic propositions (i.e. boolean properties) that are true in those states, e.g. PlanCreated from the Planner automaton;
- **Italic text** is used for the guards that annotate state transitions with the conditions which must hold for the transitions to occur, e.g. $\text{time} \leq \text{MAX\_TIME}$ from the Analyzer automaton;
- State transitions are additionally annotated with the actions executed upon taking the transitions, and these actions are also shown in sans-serif font, e.g. $\text{time}=0$ to initialise a timer in the Monitor automaton;

| Stage | Type | Description | Supporting tool(s) |
|-------|------|-------------|--------------------|
| 1     | tool supported | Timed automata controller models developed from UPPAAL templates | UPPAAL |
|       |      | Incomplete stochastic models of the controlled system and environment developed based on system specification and domain knowledge | PRISM |
| 2     | tool supported | Controller models verified to obtain controller assurance evidence | UPPAAL |
| 3     | manual | Partial assurance argument devised from GSN assurance argument pattern | – |
| 4     | manual | Controller enacted by integrating the verified controller models and platform | – |
| 5     | manual | Controlled system, controller and knowledge repository deployed | – |
| 6     | automated | MAPE control loop continually executed to ensure the system requirements | PRISM & ENTRUST controller platform |
| 7     | automated | GSN dynamic assurance argument generated | ENTRUST controller platform |

**TABLE 1**

Stages of the tool-supported instance of the ENTRUST methodology
**Bold text** is used for the synchronisation channels between two automata—these channels are specified as pairs comprising a ‘!’-decorated sent signal and a ‘?’-decorated received signal with the same name, e.g., `startAnalysis!` and `startAnalysis?` from the monitor and analyzer automata, respectively. The two transitions associated with a synchronisation channel can only be taken at the same time.

Finally, signals in angle brackets ‘⟨⟩’ are placeholders for application-specific signal names, and guards and actions decorated with brackets ‘⟨⟩’ represent application-specific C-style functions.

To specialise these model templates for a particular system and application, software engineers need: (a) to replace the signal placeholders with real signal names; (b) to define the guard and action functions; and (c) to devise the automaton regions shaded in Fig. 8 for the UUV executor. For example, for the monitor automaton the engineers first need to replace the placeholders `<sensorSignal1?>, . . . , <sensorSignaln?>` with sensor signals announcing relevant changes in the managed system. They must then implement the functions `process()`, `analysisRequired()` and `monitorCleanup()`, whose roles are to process the sensor data, to decide if the change specified by this data requires the “invocation” of the analyzer through the `startAnalysis!` signal, and to carry out any cleanup that may be required, respectively. Details about the other automata from Fig. 8 are available on our project website, which also provides implementations of these MAPE model templates in the modelling language of the UPPAAL verification tool suite [6].

**EXAMPLE 1.** We instantiated the ENTRUST model templates for the UUV system from Section 3.1 obtaining the automata shown in Fig. 9. The signal `newRate?` is the only sensor signal that the monitor automaton needs to deal with, by
reading a new UUV-sensor measurement rate (in `process()`)
and checking whether this rate has changed to such extent

observations of the controlled system [15], [22], [42], [46].
EXAMPLE 2. Fig. 10 shows the CTMC model \(M_i\) of the i-th UUV sensor from our running example. From the initial state \(s_0\), the system transitions to state \(s_1\) or \(s_0\) if the sensor is
switched on \((x_i = 1)\) or off \((x_i = 0)\), respectively. The sensor takes measurements with rate \(r_i\), as indicated by the transition \(s_1 \rightarrow s_2\). A measurement is accurate with probability \(p_i\) as shown by the transition \(s_2 \rightarrow s_3\); when inaccurate, the transition \(s_3 \rightarrow s_4\) is taken. While the sensor is
active this operation is repeated, as modelled by the transition \(s_5 \rightarrow s_1\). The model is augmented with two
reward structures. A “measure” structure, shown in a dashed
rectangular box, associates a reward of 1 to each accurate measurement taken. An “energy” structure, shown in solid
rectangular boxes, associates the energy used to switch the
sensor on \((e_i^\text{on})\) and off \((e_i^\text{off})\) and to perform a measurement \((e_i)\) with the transitions modelling these events. The model
\(M\) of the n-sensor UUV is given by the parallel composition of the n sensor models: \(M = M_1[\ldots]M_n\) and the QoS system requirements are specified using CSL as follows:

R1: \(R_{\text{measure}}[\text{C} \leq 10/\text{sp}]\)
R2: \(R_{\text{energy}}[\text{C} \leq 10/\text{sp}]\)
R3: \(\text{minimise}(w_1 E + w_2 s p^{-1})\), where \(E = R_{\text{energy}}[\text{C} \leq 10/\text{sp}]\)

where \(10/\text{sp}\) is the time taken to travel 10m at speed \(s\).
As requirement R4 is a failsafe requirement, we verify it at design time as explained in the next section, so it is not encoded into CSL.

5.2.2 Verification of Controller Models
During this ENTRUST stage, a trusted model checker is
used to verify the network of MAPE automata devised in
the previous section. This verification yields evidence that the
MAPE models satisfies a set of key safety and liveness
properties that may include both generic and application-specific properties. Table 3 shows a non-exhaustive list of
generic properties that we assembled for the current version of
ENTRUST. Although these properties are application-independent, verifying that an ENTRUST controller satisfies
them is possible only after its application-specific MAPE models were devised. This involves completing the
application-specific parts of the planner and executor
automata, and implementing the functions for the guards and
actions from all the model templates.

Additionally, automata that simulate the controller
sensors, runtime probabilistic verification engine and effectors
from Fig. 7 need to be defined to enable this verification.
The sensors, verification engine and effectors automata have to
synchronise with the relevant monitor, analyzer and
executor signals, respectively. The sensors automaton and

We used a simple one-state effectors automaton to verify the two parts of the MAPE automata from Fig. 9. These auxiliary UPPAAL automata are available on the project website.

### 5.2.3 Partial Instantiation of Assurance Argument Pattern

We used the Goal Structuring Notation (GSN) introduced in Section 2.2 to devise a reusable assurance argument pattern (cf. Section 2.3) for self-adaptive software. Unlike all existing assurance argument patterns [59], our new pattern captures the fact that for self-adaptive software the assurance process cannot be completed at design time. Instead, it is a continual process where some design features and code elements are dynamically reconfigured and executed during self-adaptation. As such, the detailed claims and evidence for meeting the system requirements must vary with self-adaptation, and thus ENTRUST assurance cases must evolve dynamically at runtime.

The ENTRUST assurance argument pattern is shown in Fig. 11. Its root goal, ReqsAchieved, states that the system requirements are satisfied at all times. These requirements are typically allocated to the software from the higher-level system analysis process, so the justifications of their derivation, validity and completeness are addressed as part of the overall system assurance case (which is outside the scope of the software assurance case). ReqsAchieved is supported by a sub-claim based on (i.e. in the context of) the current configuration (ReqsConfiguration) and by a reconfiguration sub-claim (Reconfig). That is, the pattern shows that we are guaranteeing that the current configuration satisfies the requirements (in the absence of changes) and that the ENTRUST controller will plan and execute a reconfiguration that will satisfy these requirements (should a change occur).

The pattern justifies how the system requirements are achieved for each configuration by using a sub-goal Rx-Achieved for each requirement Rx. Further, a new configuration has the potential to introduce erroneous behaviours (e.g., deadlocks). The justification for the absence of these errors is provided via the away goal NoErroneousBehaviour (described below). The pattern concludes with the goals...
The absence of controller errors. This is supported (i) by the controller verification evidence from Stage 2 of ENTRUST (cf. Fig. 9); and (ii) by the reusable platform assurance evidence, which includes (testing) evidence about the correct operation of the model checkers UPPAAL and PRISM, based on their long track record of successful adoption across multiple domains and on our own experience of using them to develop self-adaptive systems.

2) The absence of controlled system errors, covered by the ControlledSystem away goal.

The away goals SuitableSoftEngProcess and ControlledSystem are obtained following existing software assurances processes, and thus we do not describe them here. The partial instantiation of the assurance argument pattern in the last design-time stage of ENTRUST produces a partially-developed and partially-instantiated assurance argument [36]. This includes placeholders for items of evidence that can only be instantiated and developed based on operational data, i.e., the runtime verification evidence that is generated by the analysis and planning steps of the ENTRUST controller.

**Example 4.** Fig. 13 shows the partially-instantiated assurance argument pattern for the self-adaptive UUV system, in which we shaded the (partially) instantiated GSN elements. To keep the diagram clear, we only show the expansion for requirements R1 and R4, leaving R2 and R3 undeveloped. The goal R1Achieved (which needs to be further instantiated when the system configuration is dynamically selected) is supported by: (a) sub-claim R1Verified, whose associated solution placeholder R1Result remains uninstantiated and should constantly be updated by the ENTRUST controller at runtime; and (b) the away goal ReqsPreservedByPlatform described earlier in this section. The undeveloped and partially instantiated goals R2Achieved and R3Achieved have the same structure as R1Achieved. In contrast, the (failsafe) goal R4Achieved is fully instantiated because the solution R4Result, comprising UPPAAL verification evidence that R4 is achieved irrespective of the configuration of the self-adaptive system, was obtained in the second ENTRUST stage (verification of controller models), cf. Example 3.

5.2.4 Enactment of the Controller

In this stage, the controller from Fig. 7 is assembled by integrating the MAPE controller models discussed in Section 5.2.1 the ENTRUST verified controller platform and application-specific sensor, effector and stochastic model management components. The application-specific components include generic functionality such as the signals through which these components synchronise with the MAPE automata (e.g., verify? and planExecuted?). Accordingly, our current version of ENTRUST includes abstract Java classes that provide this common functionality. These abstract classes, which we made available on the project website, need to be specialised for each application. Thus, the specialised sensors and effectors must use the APIs of the managed software system to observe its state and environment, and to modify its configuration, respectively. The stochastic model management component must specialise
the probabilistic verification engine so that it instantiates the parametric stochastic models using the actual values of the managed system and environment parameters (provided by sensors) and analyses the application-specific requirements.

Example 5. To assemble an ENTRUST controller for the UUV system from our running example, we implemented Java classes that extend the functionality of the abstract Sensors, Effectors and VerificationEngine classes from the ENTRUST distribution. In addition to synchronising with the relevant application-specific signals from the MAPE automata (e.g., newRate?), the specialised sensors and effectors invoke the relevant API methods of our UUV simulator. The specialised verification engine instantiates the parametric sensor models $M_i$ from Fig. 10, $1 \leq i \leq n$, and verifies the CSL-encoded requirements from Example 2.

5.2.5 Deployment of the Self-Adaptive System

As explained in Section 4.1.3, the role of this stage is to integrate the ENTRUST controller and the controlled software system into a self-adaptive software system that is then installed, preconfigured and set running. In particular, the pre-configuration must select initial values for all the parameters of the controlled system. Immediately after it starts running and until the first execution of the MAPE control loop, the system functions as a traditional, non-adaptive software system. As such, a separate assurance argument (which is outside the scope of this paper) must be developed using traditional assurance methods, to confirm that the initial system configuration is suitable.

The newly running software starts to behave like a self-adaptive system with the first execution of the MAPE control loop, as described in the next two sections.

Example 6. For the system from our running example, we used the open-source MOOS-IvP platform (oceanai.mit.edu/moos-ivp) for the implementation of autonomous applications on unmanned marine vehicles [7], and we developed a fully-fledged three-sensor UUV simulator that is available on the ENTRUST website. We then exploited the publish-subscribe architecture of MOOS-IvP to interface the ENTRUST sensors and effectors (and thus the controller from Example 5) with the UUV simulator, we installed the controller and the controlled system on a computer with a similar spec to that of the payload computer of a mid-range UUV, and we preconfigured the system to start with zero speed and all its sensors switched off. We chose this configuration, corresponding to initial UUV parameter values $(x_1, x_2, x_3, sp) = (0, 0, 0, 0)$, to ensure that the system started with a configuration satisfying its failsafe requirement R4 (cf. Section 3.1).

5.2.6 Self-Adaptation

In this ENTRUST stage, the deployed self-adaptive system is dynamically adjusting its configuration in line with the observed internal and environmental changes. The use of continual verification within the ENTRUST control loop produces assurance evidence that underpins the dynamic generation of assurance cases in the next stage of our ENTRUST instance.

Example 7. Consider the scenario in which the UUV system from our running example comprises $n = 3$ sensors with:

7. Mission-Oriented Operating Suite – Interval Programming
8. The use of a failsafe initial configuration is our recommended approach for ENTRUST self-adaptive systems. When this is not possible, an execution of the MAPE loop must be initiated as part of the system start-up, to ensure that an initial configuration meeting the system requirements is selected.
5.2.7 Synthesis of Dynamic Assurance Argument

The ENTRUST assurance case evolves in response to the results of the MAPE process, e.g., time-triggered and event-triggered outputs of the monitor, the outcomes of the analyzer, the mitigation actions developed by the planner and their realisation by the executor. This offers a dynamic approach to assurance because the full instantiation of the ENTRUST assurance argument pattern is left to runtime, i.e., the only stage when the evidence required to complete the argument becomes available. As such, the assurance case resulting from this stage captures the full argument and evidence for the justification of the current configuration of the self-adaptive system.

EXAMPLE 8. Consider again the partially-instantiated assurance argument pattern for our UUV system (Fig. [13]). After the ENTRUST controller activities described in Example 7 conclude with the selection of the UUV configuration $\left(x_1, x_2, x_3, sp\right) = (1, 1, 0, 3.2)$ and the generation of runtime verification evidence that this configuration satisfies requirements R1–R3, this partially-instantiated assurance argument pattern is fully instantiated as shown in Fig. [15].

5.3 Self-Adaptive Service-Based System

We complete the presentation of the tool-supported instance of ENTRUST with a description of its use to engineer the second self-adaptive system introduced in Section 3.

Stage 1 (Development of Verifiable Models) We specialised our event-triggered MAPE model templates for the FX system. The resulting MAPE models are shown in Fig. [15] where the shaded areas in Planner and Executor automata indicate the FX-specific steps for assembling a plan and executing the adaptation, respectively. The implementations of all guards and actions decorated with brackets ‘$\cdot$’ (which represent application-specific C-style functions, as explained in Section 5.2.1) are available on our project website.

To model the runtime behaviour of the FX system, we used the parametric discrete-time Markov chain (DTMC) depicted in Fig. [17]. In this DTMC, constant transition probabilities derived from system logs are associated with the branches of the FX workflow from Fig. [5]. In contrast, state transitions that model the success or failure of service invocations are associated with parameterised probabilities, which are unknown until the runtime selection of the FX services. Likewise, the “price” and (response) “time” reward structures (shown in solid and dashed boxes, respectively)
Fig. 14. Verification results for requirement (a) R1, (b) R2, and (c) cost of the feasible configurations; 21 speed values between 1m/s and 5m/s are considered for each of the seven combinations of active sensors, corresponding to $21 \times 7 = 147$ alternative configurations. The best configuration (circled) corresponds to $x_1 = x_2 = 1, x_3 = 0$ (i.e., UUV using only its first two sensors) and $sp = 3.2$m/s, and the shaded regions correspond to requirement violations.

Fig. 15. Fully-instantiated assurance argument for the UUV system; the subgoals for R2Achieved and R3Achieved (not included due to space constraints) are similar to those for R1Achieved, and shading is used to show the elements instantiated at runtime.

are parametric and depend on the combination of FX services dynamically selected by the ENTRUST controller.

Finally, we formalised requirements R1–R3 in rewards-augmented probabilistic computational tree logic (PCTL), and the failsafe requirement R4 in CTL as follows:

R1: $P_{\geq 0.3}[F\ done]$

R2: $R_{\leq 5}\ [F\ done]$

R3: minimise $(w_1\ price + w_2\ time)$, where $price = R_{\leq \bar{w}_1}[F\ done] \text{ and time } = R_{\leq \bar{w}_2}[F\ done]$

R4: $A\ □ (\text{Analyzer.Analyse} \land \text{Analyzer.time}\geq 2) \rightarrow A\ □ (\text{Planner.Plan} \land \text{newConfig.Order==NoSvc})$

where ‘newConfig.Order==NoSvc’ signifies that no service is used to implement the Order operation (i.e., the operation is skipped).

Stage 2 (Verification of Controller Models) We used the model checker UPPAAL to verify that the MAPE automata network from Fig. 16 satisfies the generic controller correctness properties in Table 3, and the FX-specific CSL property R4.

Stage 3 (Partial Instantiation of Assurance Argument Pattern) We partially instantiated the ENTRUST assurance argument pattern for our self-adaptive FX system, as shown in Fig. 18.

Stage 4 (Enactment of the Controller) To assemble the ENTRUST controller for the FX system, we combined the controller and stochastic models from Stage 1 with our generic controller platform, and with FX-specific Java classes that we implemented to specialise the abstract Sensors, Effectors and VerificationEngine abstract classes of ENTRUST. The Sensors class synchronises with the Monitor automaton from Fig. 16 through the newServicesCharacteristics! signal (issued after changes in the properties of the FX services are detected). In addition, the Sensors and Effectors classes use the relevant API methods of an FX implementation that we developed as explained below. The specialised VerificationEngine instantiates the parametric DTMC model from Fig. 17 at runtime, and verifies the PCTL formulae devised in Stage 1 for requirements R1–R3.

Stage 5 (Deployment of the Self-Adaptive System) We implemented a prototype version of the FX system using Java web services deployed in Tomcat/Axis, and a Java FX
Fig. 16. FX MAPE automata that instantiate the event-triggered ENTRUST model templates

Fig. 17. Parametric DTMC model of the FX system; \( p_{MW}, p_{TA}, \ldots \), \( \text{time}_{MW}, \text{time}_{TA}, \ldots \), and \( \text{price}_{MW}, \text{price}_{TA}, \ldots \) represent the reliability (i.e. success probability), the response time and the price, respectively, of the implementations used for the MW, TA, … system services.

workflow that we integrated with the ENTRUST controller from Stage 4. Our self-adaptive FX system (whose code is available on our project website) could select from two functionally equivalent web service implementations for each of the six FX services from Fig. 5, i.e. from 12 web services with the initial characteristics shown in Table 4. For simplicity and without loss of generality, we installed the components of the self-adaptive FX system on a single computer with the characteristics detailed in Section 6.2.1, and we preconfigured the system to start by using the first web service implementation available for each service (i.e., MW\(_0\), TA\(_0\), etc.), except for the Order service. For Order, NoSvc was selected initially, to ensure that the failsafe requirement R4 was satisfied until a configuration meeting requirements R1–R3 was automatically selected by the first execution of the MAPE loop, shortly after the system started.

The remainder two stages of ENTRUST, presented next, were continually performed by the self-adaptive FX system as part of its operation.

Stage 6 (Self-Adaptation) In this stage, the self-adaptive FX system dynamically reconfigures in response to observed
ch dif form the web services it uses. Several such reconfigurations are described later in the paper, in Section 6.2.1 and in Fig. 22. To illustrate this process in detail, consider the system configuration immediately after change C from Fig. 22, where the FX workflow uses the services MW1, TA0, FA0, AL1, OR0, and NO1. This configuration is reached after the FX services, initially operating with the characteristics from Table 4, experience degradations in the reliability of MW0 (p\textsuperscript{new}\textsubscript{MW0} = 0.9), change B in Fig. 22, and in the response time of FA1 (time\textsubscript{FA1} = 1.2s, change C in Fig. 22). With the FX system in this configuration, suppose that the Market Watch service MW0 recovers, i.e., new p\textsubscript{MW0} = 0.976 as in Table 4. Under these circumstances, which correspond to change D from Fig. 22, the ENTRUST controller receives the updated characteristics of MW0 via its monitor. As the new service characteristics differ from those in the knowledge repository, the guard adaptationRequired() holds and the startAnalysis! signal is sent. The analyzer model receives the signal and invokes the runtime probabilistic verification engine, whose analysis of the FX requirements R1–R3 over the 2^6 = 64 possible system configurations (corresponding to six services each provided by two implementations) is shown in Fig. 19. As part of this analysis, configurations that violate requirements R1 or R2 (i.e., those from the shaded areas in Fig. 19 and Fig. 19), respectively) are discarded. The remaining configurations are feasible, so their cost is calculated (for \( w_1 = 1 \) and \( w_2 = 2 \)) as shown in Fig. 19. The feasible configuration using services MW0, TA0, FA0, AL1, OR0, and NO1 has the lowest cost and is thus selected as the best system configuration. Since the best and the current configurations differ, the guard adaptationRequired() holds and the analyzer invokes the planner through the startPlanning! signal to assemble a stepwise reconfiguration plan through which: (i) MW0 replaces MW1; and (ii) AL1 replaces AL0. Once the plan is ready, the executor automaton receives the startExecuting? signal and is ensuring the implementation of this plan by sending the signal changeService! to the system effectors.

Stage 7 (Synthesis of Dynamic Assurance Argument) The partially instantiated FX assurance pattern from Fig. 18 is updated into a full assurance argument after each selection of a new configuration by the ENTRUST controller. This involves using the new evidence generated by the runtime probabilistic verification engine to complete the instantiation of the assurance pattern. As an example, Fig. 20 shows the complete assurance pattern synthesised as part of the configuration change that we have just used to illustrate the previous stage of ENTRUST.

6 Evaluation

This section presents our evaluation of ENTRUST. We start with a description of our evaluation methodology in Section 6.1. Next, we detail our experimental results, and discuss the findings of the ENTRUST evaluation in Section 6.2. Finally, we assess the main threats to validity in Section 6.3.

6.1 Evaluation Methodology

To evaluate the effectiveness and generality of ENTRUST, we used our methodology and its tool-supported instance to engineer the two self-adaptive software systems from Section 3. In each case, we first implemented a simple version of the managed software system using an established development platform for its domain (cf. Example 6 and Section 5.3 – Stage 5). We then used our methodology to develop an ENTRUST controller and a partially-instantiated assurance argument pattern for the system. Next, we deployed the ENTRUST self-adaptive system in a realistic environment seeded with simulated changes specific to the application domain. Finally, we examined the correctness and efficiency of the adaptation and of the assurance cases produced by ENTRUST in response to each of these unexpected environmental changes. The experimental results are discussed in Section 6.2. The aim of our evaluation was to answer the following research questions.

RQ1 (Correctness): Are ENTRUST self-adaptive systems making the right adaptation decisions and generating valid assurance cases?

RQ2 (Efficiency): Does ENTRUST provide design-time and runtime assurance evidence with acceptable overheads for realistic system sizes?

RQ3 (Generality): Does ENTRUST support the development of self-adaptive software systems and dynamic assurance cases across application domains?
a number of assumptions. In particular, we assumed that established assurance processes could be used to construct assurance arguments for all aspects of the controlled systems from our case studies, including their correct design, development, operation, ability to respond to effector requests, and any real-time considerations associated with achieving the new configurations decided by the ENTRUST controller. As such, these aspects are outside the scope of ENTRUST and are not covered in our evaluation. We further assumed that the derivation, validity, completeness and formalisation of the self-adaptive system requirements are addressed as part of the overall system assurance cases for the two case studies, and therefore also outside the scope of our evaluation of ENTRUST.

6.2 Experimental Results and Discussion

6.2.1 RQ1 (Correctness)

To answer the first research question, we carried out experiments that involved running the UUV and FX systems in realistic environments comprising (simulated) unexpected changes specific to their domains. For the UUV system, the experiments were seeded with failures including sudden degradation in the measurement rates of sensors and complete failures of sensors, and with recoveries from these problems. For the FX system, we considered variations in the response time and the probability of successful completion of third-party service invocation. All the experiments were run on a MacBook Pro with 2.5 GHz Intel Core i7 processor, and 16 GB 1600 MHz DDR3 RAM.

For the UUV system, we described a concrete change scenario and the resulting self-adaptation process and generation of an assurance case in Examples 7 and 8, earlier in the paper. The complete set of change scenarios we used in this experiment is summarised in Fig. 21, which depicts the changes in the sensor rates and the new UUV configurations selected by the ENTRUST controller. The labels A–H from Fig. 21 correspond to following key events:

A) The UUV starts with the initial state and configuration i

As the focus of our evaluation was the ENTRUST methodology and its tool-supported instance, we necessarily made
Although a different fixed configuration may always meet requirement R1, such a configuration would violate other requirement(s), e.g. having all three UUV sensors switched on meets R1 but violates the resource usage requirement R2 at all times.

Finally, we performed experiments to assess how the adaptation decisions may be affected by changes in the weights \(w_1, w_2\) from the UUV cost \([\text{1}]\) and the energy usage of the \(n\) UUV sensors. We considered UUVs with \(n \in \{3, 4, 5, 6\}\) sensors, and for each value of \(n\) we carried out 30 independent experiments with the weights \(w_1, w_2\) randomly drawn from the interval \([1, 500]\), and the energy consumption for taking a measurement and switching on and off a sensor (i.e., \(e_i^\text{on}\) and \(e_i^\text{off}\), \(1 \leq i \leq n\)) randomly drawn from the interval \([0.1J, 10J]\). The experimental results (available, together with the PRISM-generated assurance evidence, on the project website) show that ENTRUST successfully reconfigured the system irrespective of the weight and energy usage values. In particular, if a configuration satisfying requirements R1–R3 existed for a specific change and system characteristics combination, ENTRUST reconfigured the UUV system to use this configuration. As expected, the configuration minimising the cost \([\text{1}]\) depended both on the values of the weights \(w_1, w_2\) and on the sensor energy usage. When no configuration satisfying requirements R1–R3 was available, ENTRUST employed the zero-speed failsafe configuration from requirement R4 until configurations satisfying requirements R1–R3 were again possible after a sensor recovery.

For the FX system, a concrete change scenario is detailed in Section 5.2 and the complete set of change scenarios used in our experiments is summarised in Fig. 22 where labels A–G correspond to the following events:

A) The FX starts with the initial services characteristics from Table 4 and uses a configuration comprising the services \(\text{MW}_0, \text{TA}_0, \text{FA}_0, \text{Al}_1, \text{Or}_0\) and \(\text{No}_1\), which satisfies requirements R1 and R2 and optimises R3;

B) The Market Watch service \(\text{MW}_0\) experiences a significant reliability degradation \(p_{\text{MW}_0}^{\text{new}} = 0.9\), so FX starts using the significantly more reliable \(\text{MW}_1\), and also replaces the faster \(\text{MW}_0\) with a configuration comprising the services \(\text{MW}_0, \text{TA}_0, \text{FA}_1, \text{Al}_1, \text{Or}_0\) and \(\text{No}_1\), to meet the timing requirement R2;

C) Due to an increase in response time of \(\text{Fundamental Analysis}\) service \(\text{FA}_1\) \(\text{time}_{\text{FA}_1}^{\text{new}} = 1.2s\), the FX switches to using \(\text{FA}_0\) and also replaces the \(\text{Alarm}\) service \(\text{Al}_1\) with the faster but more expensive service \(\text{Al}_0\) (to meet the timing requirement R2);

D) The Market Watch service \(\text{MW}_0\) recovers, so FX switches back to this services and also resumes using the less reliable \(\text{Alarm}\) service \(\text{Al}_1\);

E) The Technical Analysis service \(\text{TA}_0\) and the Notification service \(\text{No}_1\) exhibit unexpected degradations in reliability \(p_{\text{TA}_0}^{\text{new}} = 0.98\) and in response time \(\text{time}_{\text{No}_1}^{\text{new}} = 1s\), respectively, so the FX system self reconfigures to use the services \(\text{MW}_0, \text{TA}_1, \text{FA}_1, \text{Al}_0, \text{Or}_0\) and \(\text{No}_1\);

F) As a result of a reliability degradation in the Order service \(\text{Or}_0\) \(p_{\text{Or}_0}^{\text{new}} = 0.91\) and recovery of the Technical Analysis service \(\text{TA}_0\), the FX system replaces services \(\text{MW}_0\), \(\text{TA}_1\), \(\text{FA}_1\) and \(\text{Or}_0\) with \(\text{MW}_1\), \(\text{TA}_0\), \(\text{FA}_0\) and \(\text{Or}_1\),

### Fig. 21. Change scenarios for the self-adaptive UUV system over 2100 seconds of simulated time. Extended shaded regions indicate the sensors switched on at each point in time, and narrow shaded areas show the periodical testing of sensors switched off due to degradation (to detect their recovery).

- B) Sensor 3 experiences the degradation described in Example 7 \((p_{\text{3}}^{\text{new}} = 1)\), so the higher-rate but less energy efficient sensor 1 is switched on (allowing a slight increase in speed to \(sp = 3.2\text{m/s}\)) and sensor 3 is switched off;
- C) Sensor 3 recovers and the initial configuration is resumed;
- D) Sensor 2 experiences a degradation, and is replaced by sensor 1, with the speed increased to \(sp = 3.1\text{m/s}\);
- E) Sensor 2 recovers and the initial configuration is resumed;
- F) Both sensor 2 and sensor 3 experience degradations, so sensor 1 alone is used, with the UUV travelling at a lower speed \(sp = 2.1\text{m/s}\);
- G) Periodic tests (which involve switching sensors 2 and 3 on for short periods of time) are carried out to detect a potential recovery of the degraded sensors;
- H) Sensors 2 and 3 resume operation at nominal rates and the initial UUV configuration is reinstated.

If the UUV system was not self-adaptive, it would have to operate with a fixed configuration, which would lead to requirement violations for extended periods of time. To understand this drawback of a non-adaptive UUV, consider that its fixed configuration is chosen to coincide with the initial UUV configuration from Fig. 21 (i.e. \((x_1, x_2, x_3, sp) = (0, 1, 1, 2.8)\)) – a natural choice because manual analysis can be used to find that this configuration satisfies the UUV requirements at deployment time. However, with this fixed configuration, the UUV will violate its throughput requirement R1 whenever one or both of UUV sensors 1 and 2 experience a non-trivial degradation, i.e. in the time intervals B–C (only 13 measurements per 10m instead of the required 20 measurements, according to additional analysis we carried out), D–E (only 15 measurements per 10m) and F–H (only 7 measurements per 10m) from Fig. 21. Although a different fixed configuration may always meet...
respectively; 

G) All the degraded services recover, so the initial configuration \( MW_0, TA_0, FA_0, AI_1, Or_0 \) and No_1 is reinstated.

As in the case of the UUV system, a non-adaptive FX version will fail to meet the system requirements for extended periods of time. For example, choosing to always use the initial FX configuration from Fig. 22 would lead to a violation of the reliability requirement R1 while service \( MW_0 \) experiences a significant reliability degradation in the time interval B–D. While using service \( MW_1 \) instead of \( MW_0 \) would avoid this violation, \( MW_1 \) is more expensive but no faster than \( MW_0 \) (cf. Table 4) so its choice would increase the cost \( 2 \), thus violating the cost requirement R3 in the time interval A–B.

For each change scenario from our experiments within the two case studies (cf. Figs. 21 and 22), we performed two checks. For the former check, we confirmed that the ENTRUST controller operated correctly. To this end, we established that the change was accurately reported by the sensors and correctly processed by the monitor, leading the analyzer to select the right new configuration, for which a correct plan was built by the planner and implemented by the executor.

For the latter check, we determined the suitability of the ENTRUST assurance cases. We started from the guidelines set by safety and assurance standards, which highlight the importance of demonstrating, using available evidence, that an assurance argument is compelling, structured and valid [32, 77, 103]. Also, we considered the fact that ENTRUST has been examined experimentally but has not been tested in real-world scenarios to generate the industrial evidence necessary before approaching the relevant regulator. However, our preliminary results show, based on formal design-time and runtime evidence, that the primary claim of ENTRUST assurance cases is supported by a direct and robust argument. Firstly, the argument assures the achievement of the requirements either based on a particular active configuration or through reconfiguration, while maintaining a failsafe mechanism. Secondly, the argument and patterns are well-structured and conform to the GSN community standard [56]. Thirdly, ENTRUST provides rigorous assessments of validity not only at design time but also throughout-life, by means of monitoring and continuous verification that assess and challenge the validity of the assurance case based on actual operational data. This continuous assessment of validity is a core requirement for safety standards, as highlighted recently for medical devices [89]. As such, our approach satisfies five key principles of dynamic assurance cases [36]:

- **continuity and updatability**, as evidence is generated and updated at runtime to ensure the continuous validity of the assurance argument (e.g. the formal evidence for solution \( R1Result \) from the UUV argument in Fig. 15 which satisfies a system requirement given the current configuration);
- **proactivity**, since the assurance factors that provide the basis for the evidence in the assurance argument are proactively identified (e.g. the \( ConfigDef \) context from the UUV argument in Fig. 15 which captures the parameters of the current configuration);
- **automation**, because the runtime evidence is dynamically synthesised by the MAPE controller;
- **formality**, as the assurance arguments are formalised using the GSN standard.

In conclusion, subject to the limitations described above, our experiments provide strong empirical evidence that ENTRUST self-adaptive systems make the right adaptation decisions and generate valid assurance cases.

### 6.2.2 RQ2 (Efficiency)

To assess the efficiency of the ENTRUST generation of assurance evidence, we measured the CPU time taken by (i) the design-time UPPAAL model checking of the generic controller properties from Table 3 and (ii) the runtime probabilistic model checking performed by the ENTRUST analyzer. Fig. 23 shows the time taken to verify the generic controller properties from Table 3 for a three-sensor UUV system, and for an FX system comprising two third-party implementations for each workflow service. With typical CPU times of several minutes per property and a maximum below 12 minutes, the overheads for the verification of all controller properties are entirely acceptable.

The CPU times required for the runtime probabilistic model checking of the QoS requirements for alternative con-
The two systems differed. Finally, the ENTRUST assurance arguments for the two systems were based on evidence obtained through testing, model checking, and probabilistic model checking. Although evaluation in additional areas is needed, these results indicate that our ENTRUST instance can be used across application domains.

To assess the overall generality of ENTRUST, we note that probabilistic model checking can effortlessly be replaced with simulation in our experiments, because the probabilistic model checker PRISM can be configured to use discrete-event simulation instead of model checking techniques. Using this PRISM configuration requires no change to the Markov models or probabilistic temporal logic properties we analysed at runtime. As for any simulation, the analysis results would be approximate, but would be obtained with lower overheads than those from Fig. 24.

The uncertainties that affect self-adaptive systems are often of a stochastic nature, and thus the use of stochastic models and probabilistic model checking to analyse the behaviour of these systems is very common (e.g. [14], [19], [26], [42], [45], [48], [86], [96]). As such, our ENTRUST instance is applicable to a broad class of self-adaptive systems.

Nevertheless, other methods have been used to synthesise MAPE controllers and to support their operation. Many such methods (e.g. based on formal proof, traditional model checking, other simulation techniques and testing) are described in Section 7. Given the generality of ENTRUST, these methods could potentially be employed at design time and/or at runtime by alternative instantiations of ENTRUST, supported by different modelling paradigms, requirement specification formalisms, and tools. For example, the use of the (non-probabilistic) graph transformation models or dynamic tests proposed in [5] and [49], respectively, in the self-adaptation ENTRUST stage is not precluded by any of our assumptions (cf. Section 6.2.1), although the method chosen for this stage will clearly constrain the types of requirements for which assurance evidence can be provided at runtime.

### 6.2.3 RQ3 (Generality)

As shown in Table 5, we used ENTRUST to develop an embedded system from the oceanic monitoring domain, and a service-based system from the exchange trade domain. Self-adaptation within these systems was underpinned by the verification of continuous- and discrete-time Markov chains, respectively; and the requirements and types of changes for the two systems differed. Finally, the ENTRUST assurance

| UUV | FX |
|-----|----|
| Type | embedded system | service-based system |
| Domain | oceanic monitoring | exchange trade |
| Requirements | throughput, resource use, cost, safety | reliability, response time, cost, safety |
| Sensor data | UUV sensor measurement rate | service response time and reliability |
| Adaptation actions | switch sensors on/off, change speed | change service instance |
| Uncertainty modelling | CTMC models of UUV sensors | DTMC model of system |
| Assurance evidence before deployment | testing evidence for correct operation of trusted virtual machine; model checking evidence for correctness of MAPE controller and for UUV/FX safety requirement |
| Assurance evidence obtained at runtime | probabilistic model checking evidence for throughput, resource use and cost requirements | probabilistic model checking evidence for reliability, response time and cost requirements |

Table 5: Comparison of self-adaptive systems used to evaluate ENTRUST

As shown in Fig. 24, we also ran experiments to assess the increase in runtime overhead with the system size and number of alternative configurations, by considering UUVs with up to six sensors, and FX system variants with up to five implementations per service. Typical for model checking, the CPU time increases exponentially with these system characteristics. This makes the current implementation of our ENTRUST instance suitable for self-adaptive systems with up to hundreds of configurations to analyse and select from at runtime. However, our recent work on compositional [20], incremental [66], caching-lookahead [52] and distributed [18] approaches to probabilistic model checking and on metaheuristics for probabilistic model synthesis [53] suggests that these more efficient model checking approaches could be used to extend the applicability of our ENTRUST instance to much larger configuration space sizes. As an example, in [52] we used caching of recent runtime probabilistic model checking results and anticipatory verification of likely future configurations (i.e. lookahead) to significantly reduce the mean time required to select new configurations for a variant of our self-adaptive UUV system (by over one order of magnitude in many scenarios). Integrating ENTRUST with these approaches is complementary to the purpose of this paper and represents future work.

As shown in Table 5, we used ENTRUST to develop an embedded system from the oceanic monitoring domain, and a service-based system from the exchange trade domain. Self-adaptation within these systems was underpinned by the verification of continuous- and discrete-time Markov chains, respectively; and the requirements and types of changes for the two systems differed. Finally, the ENTRUST assurance

![Fig. 24. CPU time for the runtime probabilistic model checking of the QoS requirements after changes (box plots based on 10 system runs comprising seven changes each—70 measurements in total)](image-url)
6.3 Threats to Validity

Construct validity threats may be due to the assumptions made when implementing our simple versions of the UUV and FX systems, and in the development of the stochastic models and requirements for these systems. To mitigate these threats, we implemented the two systems using the well-established UUV software platform MOOS-IvP and (for FX) standard Java web services deployed in Tomcat/Axis. The model and requirements for the UUV system are based on a validated case study that we are familiar with from previous work [52], and those for the FX system were developed in close collaboration with a foreign exchange expert.

Internal validity threats can originate from how the experiments were performed, and from bias in the interpretation of the results due to researcher subjectivity. To address these threats, we reported results over multiple independent runs; we worked with a team comprising experts in all the key areas of ENTRUST (self-adaptation, formal verification and assurance cases); and we made all experimental data and results publicly available to enable replication.

External validity threats may be due to the use of only two systems in our evaluation, and to the experimental evaluation having been done by only the authors’ three research groups. To reduce the first threat, we selected systems from different domains with different requirements. The evaluation results show that ENTRUST supports the development of trustworthy self-adaptive solutions with assurance cases for the two different settings. To reduce the second threat, we based ENTRUST on input from, and needs identified by, the research community [24], [28], [34], [35]. In addition, we fine tuned ENTRUST based on feedback from industrial partners involved in the development of mission-critical self-adaptive systems, and these partners are now using our methodology in planning future engineering activities. Nevertheless, additional evaluation is required to confirm generality for domains with characteristics that differ from those in our evaluation (e.g., different timing patterns and types of requirements and disturbances) and usability by a larger number of users.

7 Related Work

Given the uncertain operating conditions of self-adaptive systems, a central aspect of providing assurances for such systems is to collect and integrate evidence that the requirements are satisfied during the entire lifetime. To this end, researchers from the area of self-adaptive systems have actively studied a wide variety of assurance methods and techniques applicable at design time and/or at runtime [28], [34], [80], [99], [110], [113], [118]. Tables 6 and 7 summarise the state of the art, partitioned into categories based on the main method used to provide assurances, e.g. formal proof, model checking or simulation. We consider as the main method of a study from our analysis the method that the study primarily focuses on; the approaches from these studies may implicitly use additional methods, such as testing of their platforms and tools, but this is not emphasised by their authors. We summarise the representative approaches included in each category according to their:

1) Assurances evidence, comprising separate parts for the methods used to provide assurance evidence for: (i) the correctness of the platform used to execute the controller, (ii) the correctness of the controller functions, and (iii) the correctness of the runtime adaptation decisions;

2) Methodology, comprising three parts: the engineering process (i.e. a methodical series of steps to provide the assurances), tool support (i.e., tools used by engineers to provide evidence at design time and tools used at runtime by the controller, e.g. during analysis or planning), and other reusable components (i.e. third-party libraries and purpose-built software components used as part of the controller, and other artefacts that can be used at design time or at runtime, including models, templates, patterns, algorithms).

Providing assurances for self-adaptive systems with strict requirements requires covering all these aspects, as well as an assurance argument that integrates the assurance evidence into a compelling, comprehensible and valid case that the system requirements are satisfied. Unlike ENTRUST (Table 6), the current research disregards this need for an assurance argument. We discuss below the different approaches and point out limitations that we overcome with ENTRUST.

Formal proof establishes theorems to prove properties of the controller or the system under adaptation. Proof was used to provide evidence for safety and liveness properties of self-adaptive systems with different semantics (one-point adaptation, overlap adaptation, and guided adaptation) [117]. Formal proof was also used to provide evidence for properties of automatically synthesised controllers, e.g. the completeness and soundness of synthesised behavioral models that satisfy an expressive subset of liveness properties [40] and correctness and deadlock free adaptations performed by automatically synthesised controllers [70]. Finally, formal proof was used to demonstrate the correctness of adaptation effects, e.g. proofs for safety, no deadlock, and no starvation of system processes as a result of adaptation [12], and guarantees for the required qualities of adaptations, e.g. proofs for optimised resource allocation, while satisfying quality of service constraints [1]. The focus of all these approaches is on providing assurance evidence for particular aspects of adaptation. All of them offer reusable components, however, these solutions require complete specifications of the system and its environment, and—unlike ENTRUST—cannot handle aspects of the managed system and its environment that are unknown until runtime.

Model checking enables verifying that a property holds for all reachable states of a system, either offline by engineers and/or online by the controller software. Model checking was used to ensure correctness of the adaptation functions that are modeled as interacting automata, with the verified models directly interpreted during execution by a thoroughly tested virtual machine [65]. Model checking was also used to provide guarantees for automatic controller synthesis and enactment, e.g. to assure that a synthesised controller and reusable model interpreter have no anomalies [11]. Model checking has extensively been used to provide guarantees for the effects of adaptation actions on the managed system, e.g. for safety properties of the transitions of a managed system that is modeled as
TABLE 6
Overview of related research on assurances for self-adaptive systems - part I

| Approach | Assurance evidence | Methodology | Other reusable components |
|----------|--------------------|----------------|--------------------------|
| | Controller platform | Controller functions | Adaptation decisions | Engineering process | Tool support | Other reusable components |
| Formal proof | | | |
| Adaptation semantics [117] | Proof of safety and liveness properties of adaptive programs and program compositions | Model checking algorithm | |
| Synthesis of behavioral models [40] | Proof of completeness and soundness of synthesized behavioral models | Controller synthesis technique | |
| Controller synthesis [7] | Proof that controller synthesis algorithm generates controllers that guarantee correct and deadlock free adaptations | Controller synthesis process only | |
| Correctness adaptation effects [12] | Proof of safety, no deadlock, and no starvation of system processes as a result of adaptation | Tool to generate controller offline | |
| Guaranteed qualities [1] | Proof of optimizing resource allocation under QoS constraints | Verified middleware that ensures safety and liveness of monitored system | |
| Correct adaptation functions [65] | Thoroughly tested virtual machine used to interpret and run controller models | Model checking | |
| Correctness adaptation function and enactment [11] | UPPAAL model checking of interacting timed automata to ensure controller deadlock freeness, liveness, etc. and functional system requirements | UPPAAL used to verify controller models at design time | Tested reusable virtual machine; controller model templates |
| Safe adaptation configurations [1] | Synthesised controller that is guaranteed not to be anomalous | Tool used for controller synthesis | Reusable interpreter and configuration manager for controller enactment |
| Guaranteed qualities [17] | Verification of safety properties of system transitions using a graph transformation model | Symbolic verification procedure | |
| Resilience to controller failures [23] | Probabilistic model checking of continually updated stochastic models of the controlled system and the environment to ensure non-functional requirements | PRISM verification library for analysis of stochastic system and environment models | |
| | Probabilistic model checking of resilience properties of synthesized Markov models of the managed system | Procedure to check resilience to controller failures | Reusable operational profiles to check resilience |

a graph transformation system [5], to ensure non-functional requirements by runtime verification of continually updated stochastic models of the controlled system and the environment [17], and to provide evidence for resilience properties of synthesized Markov models of the managed system [23].

Again, the focus of all the approaches is on providing assurance evidence for particular aspects of adaptation. The ENTRUST instance presented in Section 6 uses two of these techniques (i.e., [65] and [17]) to verify the correctness of the MAPE logic at design time and to obtain evidence that adaptation decisions are correct at runtime, respectively. In addition, ENTRUST offers a process for the systematic engineering of all components of the self-adaptive system, which includes employing an industry-adopted standard for the formalization of assurance arguments.

Simulation approaches provide evidence by analysing the output of the execution of a model of the system. Simulation was used to evaluate novel self-adaptation approaches, e.g., to ensure the scalability and robustness to node failures and message loss of a self-assembly algorithm [97], and to support the design of self-adaptive systems, e.g., to check if the performance of a latency-aware adaptation algorithm falls within predicted bounds [25]. Recently some efforts have been made to let the controller exploit simulation at runtime to support analysis, e.g., runtime simulation of stochastic models of managed system and environment has been used to ensure non-functional requirements with certain level of confidence [112]. The primary focus of simulation approaches has been on providing assurance evidence for the adaptation actions (either as a means to check the controller effects or to make a prediction of the expected effects of different adaptation options). The approaches typically rely on established simulators.

Testing is a standard method for assessing if a software system performs as expected in a finite number of scenarios. Testing was used to test the effectiveness of adaptation frameworks, e.g., checking whether a self-repair framework applied to a client-server system keeps the latencies of clients within certain bounds when the network is overloaded [51]. Testing was used to provide evidence for the robustness of controllers by injecting invalid inputs at the controller’s interface and use the responses to classify robustness [23]. Several studies have applied testing at runtime, e.g., to validate safe and correct adaptations of the managed system based on adapt test cases generated in response to changes in the system and environment [49]. While simulation and testing approaches can be employed within the generic ENTRUST methodology to obtain
### TABLE 7
Overview of related research on assurances for self-adaptive systems - part II

| Approach                                      | Assurance evidence | Methodology           |
|-----------------------------------------------|--------------------|-----------------------|
|                                               | Simulation         |                       |
| Evaluation novel approach [27]                | Offline simulation to ensure the scalability and robustness to node failures and message loss |                       |
| Support for design [25]                       | Offline simulations to check if the performance of a latency-aware adaptation algorithm falls within predicted bounds | OMiNet++ simulator for checking algorithm performance |
| Runtime analysis [112]                        | Runtime simulation of stochastic models of managed system and environment to ensure non-functional requirements with certain level of confidence | UPPAAL-SMC used for online simulation of stochastic system and environment models |
| Testing                                       | Offline stress testing in client-server system, showing that self-repair significantly improves system performance | Rainbow framework to realise self-adaptation |
| Test effectiveness of adaptation framework [51] | Robustness testing of controller by injecting invalid inputs at the controller’s interface and employ responses to classify robustness | Probabilistic response specification patterns for robustness testing |
| Test controller robustness [23]               | Dynamic tests to validate safe and correct adaptation of system using test cases adapted to changes in the system and environment | One-stage process for test case adaptation |
| Runtime testing [43]                         | Control-theoretic guarantees for one goal (setpoint) using automatically synthesised controller at runtime |                       |
| Other approaches                              | Controller guarantees for stability, overshoot, setting time and robustness of system operating under disturbances | ARPE tool to build online a first-order model of the system |
| Control-theoretic approaches, e.g., [27]      | Online verification of the probability that a temporal property is satisfied given a sample execution trace | Kalman filter and change point detection procedure for model updates |
| Runtime verification [53]                     | Sanity checks evaluate the correctness of resource sharing decisions made by a reasoning engine | CHAMELEON tool providing performance guarantees |
| Sanity checks [107]                           |                       |                       |

### TABLE 8
Comparison of ENTRUST to related research on assurances for self-adaptive systems

| Approach                        | Assurance evidence | Methodology            |
|---------------------------------|--------------------|------------------------|
|                                               | Engineering process | Tool support | Other reusable components |
| Generic ENTRUST methodology      | Reuse of verified application-independent controller functionality | Seven-stage process for the systematic engineering of all components of the self-adaptive system, and of an assurance case arguing its suitability for the intended application | Tools specific to each ENTRUST instance | Reusable software artefacts: controller platform, controller model templates; Reusable assurance artefacts: platform assurance evidence, generic controller requirements, assurance argument pattern |
| Tool-supported ENTRUST instance  | UPPAAL model checking of interacting timed automata models to ensure controller deadlock-freeness, liveness, etc. and functional system requirements | Assurance argument synthesised using the industry-adopted Goal Structuring Notation (GSN) standard | UPPAAL used to verify controller models; PRISM used to verify stochastic system and environment models | Reusable controller platform (virtual machine, probabilistic verification engine), timed automata controller model templates; Reusable platform assurance evidence, CTL generic controller requirements, GSN assurance argument pattern |
assurance evidence for particular aspects of self-adaptive systems, they need to be complemented by assurances for other components of a self-adaptive system and integrated in a systematic process as provided by ENTRUST.

Other approaches. To conclude, we highlight some other related approaches that have been used to provide assurances for self-adaptive systems. Recently, there has been a growing interest in applying control theory to build “correct by construction” controllers. The approach was used to automatically synthesise controllers at runtime, providing control-theoretic guarantees for stability, overshoot, setting time and robustness of system operating under disturbances [47]. This research is at an early stage, and its potential to deliver solutions for real-world systems and scenarios has yet to be confirmed. In contrast, ENTRUST relies on proven software engineering techniques for modelling and analysing software systems and assuring their required properties. Runtime verification is a well-studied lightweight verification technique based on extracting information from a running system to detect whether certain properties are violated. For example, sequences of events can be modeled as observation sequences of a Hidden Markov Model allowing to verify the probability that a temporal property is satisfied by a run of a system given a sampled execution trace [65]. Sanity checks are another approach to check the conformance of requirements of adaptive systems. Sanity checks have been used to evaluate the correctness of resource sharing decisions made by a reasoning engine [107]. Approaches such as runtime verification and sanity checks are often supported by established tools. However, these approaches provide only one piece of evidence. Such approaches can also be used by our generic ENTRUST methodology, which supports the integration of assurance evidence from multiple sources in order to continuously generate an assurance case.

Another line of related research (not specifically targeting self-adaptation and thus not included in Table 7) is runtime certification, proposed in [90] and further developed in [71], [92]. Runtime certification involves the proactive runtime monitoring of the assumptions made in the assurance case, thereby providing early warnings for potential failures. ENTRUST goes beyond the mere monitoring of assumptions, to evolving the arguments and evidence dynamically based on the runtime verification data, particularly for self-adaptive software assurance. ENTRUST also extends existing work on assurance argument patterns [37] by enabling runtime instantiation.

The ENTRUST methodology and the other research summarised in this section also build on results from the areas of configurable software, configuration optimisation, and performance tuning. For instance, symbolic evaluation has been used to understand the behaviour of configurable software systems [85], dedicated support to automatically verify the correctness of dynamic updates of client-server systems has been proposed [62], and specification languages have been devised to help program library developers expose multiple variations of the same API using different algorithms [33]. However, none of these results could be directly applied to self-adaptive software systems, which need to reconfigure dynamically in response to runtime environmental uncertainties and goal changes.

The sparsity of Tables 6 and 7 makes clear that existing approaches are confined to providing correctness evidence for specific aspects of the self-adaptive software. In contrast to existing work on assurances for self-adaptive systems, Table 8 shows that ENTRUST offers an end-to-end methodology for the development of trustworthy self-adaptive software systems. Unique to our approach, this includes the development of assurance arguments. The upper part of Table 8 shows how the generic ENTRUST methodology covers the whole spectrum of aspects that are required to provide assurances for self-adaptive systems with strict requirements. The lower part of Table 8 shows a concrete tool-supported instantiation of ENTRUST and summarises how the various assurances aspects are covered for this instance. Details about the information summarised in the table are provided in Sections 4 and 5.

8 Conclusion
We introduced ENTRUST, the first end-to-end methodology for the engineering of trustworthy self-adaptive software systems and the dynamic generation of their assurance cases. ENTRUST and its tool-supported instance presented in the paper include methods for the development of verifiable controllers for self-adaptive systems, for the generation of design-time and runtime assurance evidence, and for the runtime instantiation of an assurance argument pattern that we devised specifically for these systems.

The future research directions for our project include evaluating the usability of ENTRUST in a controlled experiment, extending the runtime model checking of system requirements to functional requirements, and reducing the runtime overheads by exploiting recent advances in probabilistic model checking at runtime [18], [20], [44], [52], [66]. In addition, we are planning to explore the applicability of ENTRUST to other systems and application domains.
