Athletic performance relies on tendons, which enable movement by transferring forces from muscles to the skeleton. Yet, how load-bearing structures in tendons sense and adapt to physical demands is not understood. Here, by performing calcium (Ca2+) imaging in mechanically loaded tendon explants from rats and in primary tendon cells from rats and humans, we show that tenocytes detect mechanical forces through the mechanosensitive ion channel PIEZO1, which senses shear stresses induced by collagen-fibre sliding. Through tenocyte-targeted loss-of-function and gain-of-function experiments in rodents, we show that reduced PIEZO1 activity decreased tendon stiffness and that elevated PIEZO1 mechanosignalling increased tendon stiffness and strength, seemingly through upregulated collagen cross-linking. We also show that humans carrying the PIEZO1 E756del gain-of-function mutation display a 13.2% average increase in normalized jumping height, presumably due to a higher rate of force generation or to the release of a larger amount of stored elastic energy. Further understanding of the PIEZO1-mediated mechanoregulation of tendon stiffness should aid research on musculoskeletal medicine and on sports performance.
the unstretched condition, we detected sparse spontaneous Ca\textsuperscript{2+} signals; however, after stretching from 0–10% strain, we observed a tissue-wide Ca\textsuperscript{2+} response (Fig. 1b and Supplementary Videos 1 and 2), with Ca\textsuperscript{2+} signals lasting 28.2 ± 16.5 s (mean ± s.d.). By testing different strain rates, we noticed distinct Ca\textsuperscript{2+} dynamics. At a low strain rate, each tenocyte exhibited multiple Ca\textsuperscript{2+} signals, whereas, at a high strain rate, they displayed only a single Ca\textsuperscript{2+} response after tendon stretching (Fig. 1c and Supplementary Fig. 1). Furthermore, with increasing strain rate, higher tissue stretch was required to elicit a Ca\textsuperscript{2+} response in 50% of the cells (Fig. 1d). This strain rate dependency can be partially explained by a time lag between stimulus and Ca\textsuperscript{2+} signal. Mechanical thresholds were found at (from low to high strain rate): 1.96 ± 0.33% strain (n = 7 fascicles), 2.72 ± 0.33% strain (n = 7 fascicles) and 3.62 ± 0.38% strain (n = 6 fascicles). Statistical analysis was performed using one-way ANOVA with testing for multiple comparisons (Tukey test).

The stretch-induced Ca\textsuperscript{2+} response was confirmed using two-photon fluorescence lifetime imaging (FLIM), using which we also determined the absolute Ca\textsuperscript{2+} concentrations in tissue-resident tenocytes (Supplementary Fig. 2) after OGB-1 (Oregon Green
Shear stress triggers Ca\(^{2+}\) signals in isolated tenocytes. During tissue stretching, collagen fibres—the load-bearing elements of the extracellular matrix—slide past each other\(^{11}\). Tenocytes reside between these fibres and are therefore exposed to mechanical shear. As fibre sliding is the predominant mechanism enabling the extension of tendon fascicles\(^{18}\), we wondered whether shear stress could be the primary mechanical stimulus for tenocytes. We therefore quantified the fibre sliding by tracking cells from image sequences obtained at low strain rates and by comparing inter fibre displacement (Fig. 2a) and, using a physical model, we calculated the resulting shear stress, which ranged between 2 Pa and 6 Pa depending on the cell height (Fig. 2b). Our analysis suggests that shear-stress levels may vary across cellular domains of tenocytes, probably being highest around narrow protrusions and lowest around the cell body. To test our prediction, we developed a microfluidics flow chamber that enables simultaneous Ca\(^{2+}\) imaging and shear stress stimulation of isolated primary tenocytes stained with Fluo-4 (Fig. 2c and Supplementary Fig. 3; further details are provided in the Methods). Exposing tenocytes to a shear stress of 5 Pa, which occurs during tissue stretching, triggered a prominent Ca\(^{2+}\) response (Fig. 2d and Supplementary Video 4). The magnitude of shear-stress stimulus determines the percentage of responsive cells (Fig. 2e) as well as the amplitude and duration of the Ca\(^{2+}\) response (Supplementary Fig. 4). A Ca\(^{2+}\) response in about 50% of tenocytes is induced by a shear stress of 3.3 Pa, which falls well within the range of the calculated shear stress that occurs during tissue stretching (Fig. 2b). Together, this confirms the role of shear stress as a key mechanical stimulus for tenocytes, which show similar responsiveness across anatomical regions (Fig. 2f).

We noticed that Ca\(^{2+}\) signals typically start at the cell periphery both in isolated and in tissue-resident tenocytes (Fig. 2g). This
is consistent with our physical model that predicts that narrow regions (that is, protrusions) experience the highest levels of shear stress.

**PIEZO1 is required for the shear-stress-induced response in tenocytes.** As mechanotransduction relies on membrane proteins that convert mechanical stimuli into a biological signal\(^\text{36}\), we wondered whether shear stress in tenocytes activates mechanosensitive membrane channels mediating the Ca\(^{2+}\) influx. To test this, we performed mechanical stimulation in Ca\(^{2+}\)-free medium and observed no overt Ca\(^{2+}\) response in tissue-resident and isolated tenocytes (Fig. 3a). However, reperfusion with control medium containing Ca\(^{2+}\) restored the stimulus-evoked responses (Fig. 3a), suggesting a channel-mediated mechanism.

**Fig. 3 | PIEZO1-mediated shear-stress response in human tenocytes.** a. Mechanically induced Ca\(^{2+}\) signals are nearly absent in Ca\(^{2+}\)-free medium (containing 2 mM EGTA and 2 mM MgCl\(_2\) instead of CaCl\(_2\)) but are restored in control medium, both in situ (one cycle stretch to 2.7% strain at 0.1% strain per s; n = 7 fascicles from rat tails) and in vitro (shear-stress stimulation; n = 12 chambers, cells from semitendinosus tendons of 3 human donors). Statistical analysis was performed using paired Student’s t-tests. b. The highest expressed candidate genes associated with mechanosensitive ion channel characteristics selected from RNA-sequencing experiments with mouse tail tendons\(^\text{37}\) and human Achilles tendons\(^\text{38}\). -tests. The highest expressed candidate genes associated with mechanosensitive ion channel characteristics selected from RNA-sequencing experiments with mouse tail tendons\(^\text{37}\) and human Achilles tendons\(^\text{38}\). The corresponding Ca\(^{2+}\) signals over time for each candidate, n ≥ 10 chambers were tested with cells from n = 3 human donors (semitendinosus tendons). f. The corresponding Ca\(^{2+}\) signals over time for PIEZO1-knockout tenocytes and no-target control tenocytes (averaged over all single segmented cells for the n = 3 human donors). g. The corresponding mean amplitude of the Ca\(^{2+}\) signals observed in the candidate knockouts. PIEZO1-depleted cells show a reduced amplitude of the Ca\(^{2+}\) signals. h. Two additional PIEZO1 knockouts generated using different CRISPR-guided RNAs (395 and 786 indicate the two different sites targeted by CRISPR–Cas9) confirm the reduced shear-stress response. n ≥ 4 chambers, cells from a human semitendinosus tendon. Unless indicated otherwise, statistical analysis was performed using one-way ANOVA with testing for multiple comparisons (Dunnett test). Replicates are biological. Data are mean ± s.e.m.
To identify the responsible ion channel, we focused on candidates associated with mechanosensitive cation channel characteristics that are highly expressed in both mouse tail tendons and human Achilles tendons (Fig. 3b). Using CRISPR–Cas9 genome editing, we generated efficient knockdowns of the selected genes in human primary tenocytes and tested their mechanosensitive response (Fig. 3c,d). From all examined knockdowns, only cells depleted of PIEZO1, which is known to be a shear sensor, showed a significant reduction in the shear-stress response (Fig. 3e–g). This was further corroborated by analysing additional CRISPR-guided RNAs targeting different regions of PIEZO1 (Fig. 3h), thereby also precluding the contribution of potential off-target effects. Moreover, we obtained similar results with CRISPR–Cas9-mediated Piezo1 knockdowns in rat tenocytes isolated from tail tendon fascicles (Supplementary Fig. 6a–e). This suggests that PIEZO1, which is an abundantly expressed ion channel in tendon tissues (Supplementary Fig. 6f), is the crucial shear-stress sensor in tenocytes.

Next, to further assess whether PIEZO1 also mediates mechanosensing in tissue-resident tenocytes, we generated tenocyte-targeted, conditional Piezo1 knockout mice (Piezo1<sup>fl/fl</sup>) by crossing mice expressing the tamoxifen-sensitive Cre-recombinase CreERT2 under the Scleraxis promoter (Scx-creERT2)<sup>+</sup> with mice carrying the loxP-flanked Piezo1 alleles. Scx-creERT2;Piezo1<sup>fl/fl</sup> pups were injected at postnatal days P1–P3 with tamoxifen (Fig. 4a), which led to a 40% reduction in Piezo1 mRNA expression in tail tendon fascicles from 7–13-week-old Piezo1<sup>fl/fl</sup> mice compared with their Piezo1<sup>+/+</sup> littermate controls (Fig. 4b). Even with only a partial reduction in Piezo1 expression, fascicles from Piezo1<sup>fl/fl</sup> mice and their resident tenocytes showed a reduced stretch-induced Ca<sup>2+</sup><sup>+</sup> response compared with littermate controls (Fig. 4c,d). This loss-of-function experiment provides further support that PIEZO1 is a tendon mechanosensor.

PIEZO1 activity regulates the biomechanical properties of tendons. To investigate the role of PIEZO1 in tendons, we performed in vitro and in vivo experiments. First, using ramp-to-failure tests, we characterized the biomechanical properties of the tail tendon fascicles from Piezo1<sup>+/+</sup> mice and littermate controls. We found that PIEZO1 knockout mice exhibited a 10% reduction in stiffness in fascicles from Piezo1<sup>+/+</sup> mice and their resident tenocytes showed a reduced stretch-induced Ca<sup>2+</sup><sup>+</sup> response compared with littermate controls (Fig. 4e,f). This effect was not caused by differences in the diameter of the fascicles (Fig. 4g), suggesting that PIEZO1 regulates the tendon tissue stiffness.

To further examine this PIEZO1 function, we wondered whether recurrent PIEZO1 activation in tenocytes is sufficient to adjust tissue stiffness in tendons. In cultured tendon fascicles, we first confirmed that pharmacological activation of PIEZO1 by the specific agonist...
Yoda1 (ref. 41) triggers a robust Ca\textsuperscript{2+} response in tendon-resident tenocytes (Supplementary Fig. 6g and Supplementary Video 5). Next, we maintained tendon fascicles from rat tails in our custom bioreactor\textsuperscript{12} with minimal loading to preserve tissue integrity\textsuperscript{12} and stimulated tenocytes with 5 µM Yoda1 for 30 min every 3 d for 2 weeks (mimicking exercise; Fig. 5a). To characterize changes in biomechanical properties over time, we cut each tendon fascicle in two, tested the first half at day 0 and the second half after the stimulation paradigm at day 16 (Fig. 5a). By comparing the ramp-to-failure tests of the two time points, we noticed that stiffness and strength...
were significantly higher in the Yoda1-stimulated fascicles relative to the control fascicles (Fig. 5b). However, fascicle diameter was not affected (Fig. 5b). Yoda1-stimulated fascicles showed a 4.1% average stiffness increase in the 16d of culture. Interestingly, in humans, a 14-week exercise intervention (four-times a week) with high-magnitude tendon strain induced a 36% increase in Achilles tendon stiffness, corresponding to a 5.9% increase in 16d. Thus, our data suggest that the tissue stiffness adaptation found in vitro is comparable to in vivo exercise effects.

Moreover, at the gene expression level, Yoda1 stimulation of the fascicles induces an upregulation of the collagen cross-linking enzyme LOX but not of type-I collagen (Fig. 5c). A similar gene expression profile was also observed after stretching four times to 2% (Fig. 5c), which corresponds to the mechanical threshold identified in our Ca2+-imaging experiments (Fig. 1d). This shows a notable degree of overlap between pharmacological PIEZO1 stimulation and mechanical stimulation of tendon fascicles.

To verify whether increased PIEZO1-mediated mechanosignalling regulates tendon stiffness also in vivo, we analysed tendons from mice carrying a Piezo1 gain-of-function (Piezo1GOF) mutation equivalent to a human PIEZO1 gain-of-function mutation (R2456H)28. These mice express an overactive PIEZO1 that elicits stronger Ca2+ signals after channel activation due to a longer inactivation time31. Ramp-to-failure experiments with tail tendon fascicles showed on average a 9% increase in stiffness (Fig. 5d), which is consistent with the role of PIEZO1 in regulating the mechanical properties observed in vitro and in Piezo1GOF mice. We next wondered whether tendons that are critical for power performance (that is, load-bearing tendons) exhibit a more-pronounced phenotype as they are subjected to higher mechanical loads. We therefore tested the plantaris tendons (foot flexor tendon), and found an average increase in stiffness and strength of 19% and 17%, respectively, in Piezo1GOF mice compared with wild-type littersmates, while the macroscale tendon morphology remained unchanged (Fig. 5e,f). These biomechanical differences were particularly prominent at high tendon strains and can probably be attributed to a tenocyte-specific effect, but we cannot rule out other contributing factors as these mice are constitutive Piezo1GOF mice (gain-of-function mutation in all tissues). However, given that PIEZO1 activation in tissue-resident tenocytes regulates the stiffness of tendon explants (Fig. 5b) and tenocyte-targeted Piezo1GOF mice show tail tendon fascicles with reduced stiffness (Fig. 4e), our data indicate that the tendon phenotypes in Piezo1GOF mice are primarily caused by a tenocyte-specific effect. Interestingly, load-bearing tendons of Piezo1GOF mice revealed tissue adaptations that are very similar to differences found in tendons of sprinters compared with endurance runners and non-active individuals.

PIEZO1 regulates tissue stiffness by adjusting collagen cross-linking. To investigate the mechanisms that are involved in regulating the tendon mechanical properties in Piezo1GOF mice, we first analysed the collagen fibrils—the load-bearing microstructures of tendons28. However, tendons of Piezo1GOF mice revealed no overt differences in fibril size distribution compared to their wild-type littersmates (Fig. 6a–c). Thus, elevated mechanosignalling by PIEZO1 regulates tendon stiffness and strength without inducing hypertrophic collagen production. Similarly, exercise-induced increases in tendon mechanical properties were not associated with changes in collagen fibril morphology41. This probably indicates that the regulation of tendon stiffness and strength in response to mechanosignalling may be induced by a denser collagen cross-linking44. To address this, we performed differential scanning calorimetry measurements and assessed the tissue thermal stability, which depends on the cross-link density45. Tendons from Piezo1GOF mice showed an elevated transition enthalpy, demonstrating an increased thermal stability compared with their wild-type littersmates (Fig. 6d). Thus, this finding indicates an elevated cross-link density in tendons from Piezo1GOF mice. Moreover, using two-photon microscopy we observed an increased autofluorescence signal associated with the pyridinoline-cross-links relative to the second-harmonic-generation signal associated with the collagen matrix (Fig. 6e). Although little is known about the specific contribution of individual cross-links to the mechanical properties of tendons, our data suggest a denser pyridinoline-cross-link network in the tendons of Piezo1GOF mice.

PIEZO1 activity influences jumping performance in humans. Strong, stiff tendons are critical for high physical performance and we wondered whether our observed PIEZO1-mediated adaptations in tendon stiffness and strength could be relevant for human athletic performance. In fact, about one out of three individuals of African descent carries a PIEZO1GOF mutation known as E756del, which has been associated with malaria resistance and represents the most abundant PIEZO1GOF mutation identified to date—it is particularly common in West African populations46. Whether the E756del allele is overrepresented in elite athletes is unknown. Although self-reported race serves as a poor proxy for genetic ancestry47,48, athletes hailing from countries with high E756del prevalence disproportionately populate the ranks of elite sprinters and jumpers49–51. But could human E756del carriers also present tendon adaptations that associate with athletic performance? We addressed this question in a double-blind study in which we investigated Achilles tendons of 65 healthy African Americans and assessed their jumping performance.

Genotyping identified 20 heterozygous and 2 homozygous E756del carriers, and 43 non-carrier controls (Fig. 7a). We observed comparable demographics and whole-body morphometry between E756del carriers and non-carriers, with no differences in age, height, weight, physical activity or sports participation (Fig. 7b and Supplementary Fig. 7). Ultrasound-based assessment of the Achilles tendon morphology showed no significant differences in tendon cross-sectional area and the length between E756del carriers and non-carriers (Fig. 7c,d), which is consistent with the unchanged tendon morphology observed in Piezo1GOF mice (Fig. 5d). As the tendon phenotype in Piezo1GOF mice was prominent at high degrees of tendon loading, we speculated that human E756del carriers may show athletic differences in exercises that evoke high tendon loading. We therefore measured the participant’s maximal jumping performance in two related jumps, namely, a countermovement jump (CMJ) and a drop countermovement jump (DCMJ) (Fig. 7e). The latter differs solely by an initial drop from a height of 20 cm, which leads to greater mechanical loads in the Achilles tendon42–43. Importantly, as we anticipated a high variability in performance between participants, we chose a study design that would enable an intradividual comparison using the two jumping modalities to evoke different levels of tendon loading (CMJ < DCMJ) to properly address differences in tendon-loading exercises between groups. Indeed, the overall performance varied highly between individuals (Fig. 7f). However, the intradividual comparison revealed that E756del carriers performed significantly better in DCMJ, which evokes higher tendon loading, compared with CMJ, whereas non-carrier controls performed similarly in both jumps (Fig. 7f). By accounting for the interindividual jumping variability with the normalization of individual DCMJ to CMJ, we found an average performance of 110.9% in E756del carriers that significantly exceeded the average 97.7% reached by non-carriers (Fig. 7g). Thus, E756del carriers showed a net 13.2% average increase in normalized jumping performance compared with non-carriers, presumably due to a higher rate of force development (body acceleration) or a greater capacity of tendons to store and return elastic energy. Indeed, when converting the jump height into potential energy (that is mass × gravitational acceleration × jump height), we found that E756del carriers effectively stored and returned the drop energy (+8.1 J on average), whereas...
the non-carriers did not (−1.7 J on average; Fig. 7b). Accounting for the energy return of E756del carriers against the energy dissipation of non-carriers, E756del carriers showed on average a significantly increased net energy return of 9.8 J. Thus, the E756del mutation probably influences sports performances that rely on the power output generated with high tendon loading, such as sprinting and jumping.

**Discussion**

In tendon mechanotransduction, it has been hypothesized that mechanical forces are converted into biological signals by mechanically activated membrane proteins. Isolated tenocytes are sensitive to pipette indentation and show increased frequency of spontaneous Ca$^{2+}$ signals after a mechanical stimulation. However, evidence of acute responses to physiologically relevant mechanical stimuli and the underlying molecular sensing mechanisms is lacking.

We developed a microscope-compatible functional imaging setup to enable the direct observation of tenocytes during tissue stretching and harnessed it to characterize tendon mechanotransduction by Ca$^{2+}$ imaging. After tissue stretching, we observed that tenocytes exhibit simultaneous Ca$^{2+}$ signals occurring tissue-wide, whereas, in the unstrained condition, they show only a few sparse spontaneous Ca$^{2+}$ signals. Thus, the tissue-wide spatiotemporal Ca$^{2+}$ profile differs clearly during a mechanical stimulus, probably triggering a mechanobiological response of the tissue. Furthermore, we noticed that, at a low strain rate, less stretch was required to elicit the response in tenocytes. This phenomenon might explain why physical rehabilitation strategies based on slowly performed resistance training show improved outcomes when treating tendinopathies. Our data suggest that these improvements might arise from an optimal compromise between maximizing cellular stimulation while minimizing tissue strains and loads.

Moreover, we identified shear stress as a key mechanical stimulus by determining the shear-stress levels that occur during tissue stretching, applying them to isolated primary rat and human tendon cells and finding tight activation limits in vitro and in situ. By combining functional Ca$^{2+}$ imaging with CRISPR–Cas9 screening and in vivo tenocyte-targeted loss of function, we found that PIEZO1 is a tendon mechanosensor that is crucial for shear-stress-induced Ca$^{2+}$ signals.

To investigate the role of this ion channel in tendons, we analysed the effect of reduced as well as elevated PIEZO1 mechanosignalling in tendons of rodents. Tenocyte-targeted Piezo1−/− mice showed tail tendon fascicles with reduced stiffness. By contrast, in vitro pharmacological PIEZO1 stimulation and in vivo PIEZO1 overactivity increased tendon stiffness and strength. Surprisingly, these changes do not seem to result from a hypertrophic tissue response; instead,
they are probably caused by collagen cross-linking, as we found elevated thermal stability and autofluorescence associated with pyridinoline-cross-links in tendons from Piezo1GOF mice. This is consistent with the gene expression profile triggered by both pharmacological PIEZO1 activation and mechanical stretching that revealed an upregulation of collagen cross-linking enzymes but not...
of type-I collagen. Thus, our data indicate that PIEZO1 regulates the tissue stiffness by adjusting the collagen cross-linking. This mechanism probably modulates the relative motions of collagen fibres and thereby adjusts the shear stress on cells according to the shear sensor—PIEZO1—signalling. Such tendon tissue adaptations presumably imply a tenocyte mechanostat behaviour, that is, a feedback mechanism that aims to maintain optimal shear-stress stimuli (Fig. 8). An adapting cross-link network might also explain why exercise has very little to no effect on tissue- and fibril-morphology, and why the collagen matrix has a low turnover.

The high prevalence of the PIEZO1 GOF E756del allele in the African population provides the opportunity to study the function of PIEZO1 in humans. The E756del mutation is particularly common in populations of West Africa, probably due to the potential protection it affords against malarial infection. In addition to this potential role, our evidence suggests that the E756del mutation affects human athletic performance. Specifically, E756del carriers perform significantly better than non-carriers in jumping manoeuvres that include high degrees of tendon loading and of energy storage and return. This performance mechanism is presumably enhanced in tendons of which biomechanical characteristics are governed by an overactive PIEZO1, as we observed an increase in energy return in E756del carriers. Although jumping performance is enabled by the muscle–tendon unit, note that skeletal muscle is probably not affected by the E756del mutation due to the very limited Piezo1 expression in muscle tissue (Supplementary Fig. 6f).

Beyond implications for athletic performance, PIEZO1 may represent a therapeutic target in clinical indications for which physical rehabilitation is currently prescribed. Tendon pathologies are a common human medical condition, due to the high mechanical demands and the low intrinsic healing capacity of tendon tissues. They account for a substantial portion of musculoskeletal diseases, which represent the second leading cause for years lived with disability worldwide. Our data suggest that pharmacological activation of PIEZO1 stimulates tissue reinforcement mechanisms that may be relevant to treatment of diseased and/or mechanically inferior tendons, perhaps mimicking the effects triggered by...
exercise-based physical therapy. Although this is speculative and would require substantial preclinical investigation, the identification of P2E10 as a druggable target to drive tissue adaptation could open new paths for clinical treatment of tendon disorders.

Methods

Ca²⁺ imaging of ex vivo tendon fascicles during stretching. Tendon fascicles were gently extracted from the tail of skeletally mature female Wistar rats (aged 14–18 weeks; approval by the Veterinary Office of the Canton of Zurich, ZH235/16). Rat tail tendon fascicles were stained with 5 μM Fluo-4 AM (Thermo Fisher Scientific, F14217) for 2 h at 29°C and 3% O₂ in a modified Krebs–Henseleit solution (KHS) containing 126 mM NaCl, 3 mM KCl, 2 mM CaCl₂, 2 mM MgSO₄, 1.25 mM NaH₂PO₄, 26 mM NaHCO₃, and 10 mM glucose. Single tendon fascicles were subsequently mounted onto a custom-designed tensile stretching device (equipped with two motorized and a 20 N load cell) that was placed onto the stage of an iMic widefield microscope (Thermo Fisher Scientific)⁶⁷. During the stretching protocols, fascicles were continually perfused with KHS that was preheated to 29°C and steadily aerated with a gas mixture containing 95% N₂ and 5% CO₂ to maintain 3% O₂ and constant pH levels. Images were acquired using a ×10/0.4 NA objective with excitation set at 488 nm wavelength and 100 ms exposure time. Before the stretching protocols, fascicles were preconditioned five times to 1.0% initial length L₀ (10 mm mounting length from clamp to clamp). The cross-sectional area was determined using the diameter (assuming a round cross-section) at crimp disappearance and L₀ was defined at 1 MPa tissue stress. Tissue strain was defined as (L – L₀)/L₀, as a percentage, with sample length L. Tissue stress was calculated by dividing the force (N) through the cross-sectional area.

To investigate the cellular response to tissue stretching, single fascicles were stretched at three different strain rates (low, 0.01% strain per s; medium, 0.1% strain per s; high, 1.0% strain per s) from 0% to 10% strain. Baseline activity was averaged the fluorescence signal within a 5 μm radius surrounding the centroids of individual cell nuclei were identified and tracked in a six-channel Picoquant HydraHarp 400 together with the TrackMate imageJ plugin⁶⁷. Individual cell nuclei were identified and tracked in images into 6 subimages and applied motion correction in each subimage. Ca²⁺ signals, tendon fascicles were subjected to one cycle of 2.7% strain at 30% strain per s.

Time-lapse images were analysed using the following steps. Cell movements were tracked with Imaris v.7.7 (Bitplane) and the exported displacements were further processed using custom software (MATLAB R2016a) that divided the images into 6 × 6 subimages and applied motion correction in each subimage. Ca²⁺ events were automatically detected and measured in the stabilized subimages using CHIPS (Cellular and Hemodynamic Image Processing Suite)⁶⁷. Fibre sliding was calculated from the relative displacements (in the axial direction) of the cells on adjacent fibres (for example, fibre u and v): ΔL = ∑ uᵢ − vᵢ/ L₀, u and v are the respective cell numbers of the adjacent fibres and L₀ is the fibre length⁶⁷. The Ca²⁺ responses of individual tendon fibres (Sci-csrER72, Piezo1/Cα² mice and littermate controls (Piezo1−/− mice) was investigated after staining for 2 h with 5 μM Fluo-4 AM and NuclBlue (Thermo Fisher Scientific, R37605). Images were taken using a ×10/0.4 NA objective and excitation of 390 nm (cell nuclei) and 488 nm (Ca²⁺ signal) during the following protocols: fascicles were preload to 0.025N (0% strain), subsequently stretched from 0% to 2% strain at 1% strain per s and then kept at 2% strain. The Ca²⁺ responses of individual cells were analysed using the TrackMate imageJ plugin¹. Individual cell nuclei were identified and tracked in the images acquired at 390 nm and the cellular Ca²⁺ responses were calculated by averaging the fluorescence signal within a 5 μm radius surrounding the centroids of individual nuclei in the corresponding images acquired at 488 nm. Further analyses were performed using a custom R script. Cells that showed an increase in Ca²⁺ signal ΔF/F > 1.5 with in 30 s from the start of the stretching were categorized as active.

FLIM in tendon fascicles. Isolated rat tail tendon fascicles were stained with 20 μM cell-permeable OGB-1 (Thermo Fisher Scientific, O6806) for 2 h in KHS at 29°C and 3% O₂, and mounted on our tensile stretching device placed on the stage of a two-photon microscope and continually perfused with KHS during imaging. FLIM was performed on an upright Leica TCS SP8 FLIM two-photon microscope equipped with a tunable (680–1300 nm) 80 MHz infrared laser (Insight DS+ Dual, Spectra Physics) and four non-descanned FLIM-enabled hybrid detectors. On the non-descanned detectors, the following emission band-pass filters were used: 560/40 nm, 585/40 nm and 620/40 nm. FLIM data was collected in four channels 525/50 nm and 585/40 nm were used for the FLIM analysis. A 2.6 mm working distance Leica HC IPO was x25/0.1 NA water-immersion objective was used for imaging. Time-correlated single-photon counting (TCSPC) was performed using a six-channel PicoQuant HydraHarp 400 together with the PicoQuant Standard software package. Femtosecond infrared laser pulses enabled efficient two-photon fluorescence excitation and emission from a thin focal plane in the core of a tendon fascicle (around 30–100 μm deep in the tissue). A laser wavelength of 915 nm and a maximum laser power of 12.5 mW measured after the objective were used to avoid any signs of phototoxicity. To avoid photo-induced effects as well as statistical pile-up effects in the TCSPC histograms, the photon-count rates on the detectors were always kept below 1% of the excitation imaging. An integration of 30 μs in width and 80–110 μs in height was used with a scanner frequency of 400 Hz.

The Ca²⁺ calibration buffer kit from Thermo Fisher Scientific (C30088MP) was used in combination with the cell-impermeable Ca²⁺ indicator OGB-1 at 1 μM to calibrate the [Ca²⁺] landscape. However, data analysis and statistics were performed using the raw data, not the filtered pixel maps.

Mathematical model for shear-stress prediction in tenocytes. To predict the shear stress experienced by tenocytes during tissue stretching, we applied a numerical model that assumes cell heights (h) between 1–10 μm and that assumes that individual tenocytes span the distance between two adjacent collagen fibres⁶⁷. Shear stress in tenocytes is generated by unilateral collagen fibre displacement, which leads to transverse displacement of the cell body. By definition, the shear stress (τ) arises through the application of a force (F) parallel to the cross-section over a certain surface (A) and is equal to the shear modulus (G) of the material multiplied by the shear strain (γ). The shear strain is defined as the transverse displacement (Δx) of the material divided by the initial height of the material (h): τ = Δx/ h = G × γ. The shear modulus was previously⁶⁷ estimated to be around G = 1.5 Pa and the transverse material displacement (Δx) was calculated from the fibre sliding (s) and the fibre length (ls = 900 μm, corresponding to the width of the field of view). This enables the estimation of shear stresses acting on tenocytes resulting from unilateral collagen fibre sliding.

Primary human and rat tenocyte cultures. Tendon cells were isolated either from fragments of human tendons (Ilexor digitorum, gracilis and semitendinosus) collected from female and male patients (between 24 and 58 years of age) undergoing treatment at the University Hospital Balgrist (permission 2015–0089 from the institutional review board of the Canton of Zurich and patient-informed consent) or from tail tendon fascicles of skeletally mature female Wistar rats (aged 14–18 weeks; approval by the Veterinary Office of the Canton of Zurich, ZH235/16). Next, tendon tissues were digested with 2 mg ml⁻¹ collagenase D (Roche, 1108886001) in Dulbecco’s modified Eagle’s medium (DMEM/F12, Difco) supplemented with 1% penicillin–streptomycin (Gibco, 15290–018) and 1% penicillin–strepnomycin (Sigma-Aldrich, P0781) for around 30 min at 37°C in a humidified atmosphere of 5% CO₂. Isolated cells were cultured on tissue culture plastic in DMEM/F12 with 10% heat-inactivated fetal bovine serum (Gibco, 10500) for 1–2 weeks and subsequently cryopreserved in liquid nitrogen until the start of the experiments.

Ca²⁺ imaging during application of shear stress on isolated tenocytes using flow chambers. Custom-made flow chambers were fabricated using the following procedure. A microscope slide was washed with ethanol. Data acquisition of polydimethylsiloxane (PDMS, Sylgard 184 Silicone Elastomer Kit, Dow Europe) was deposited in its centre. A silanized PDMS stamp that was moulded from the negative of the microgroove pattern (10 μm depth/ridge width/pitch) was then placed on top. The assembly was subsequently cured at 70°C for 6 h before detaching the stamps. PDMS microgrooves were chemically activated using two consecutive treatments of 0.1 M HCl and 0.1 M H₂O₂ for 6–9 h and then the Cu(II)-amine modified water-soluble polymer 6-(4′-azido-2′-nitrophenylamino)hexanolate (CovaChem, 13414) in 50 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (Seraglob, K 2101) under
ultraviolet light for 10 min. Substrates were then washed three times with sterile phosphate-buffered saline (PBS) and coated with 30 μg/ml collagen I (Corning, 354249) in PBS overnight at 4°C, before being washed three times with deionized water and air dried. Finally, a block of PDMS containing a canal (height, 0.4 mm; width, 5 mm; length, 30 mm) was glued on top of the microscope slide, centring the microgrooved path in the middle of the canal. A fine layer of PDMS containing additional 0.1% platinum-divinyltetramethyldisiloxane (abcr, 146697) was used as glue and cured at 45°C for 2 h.

Tissues were seeded in the flow chamber at a density of 38,000 cells per cm² and incubated at 29°C under 5% CO₂ and 3% O₂ overnight. Staining for 2 h with 1 μM Fluo 4-AM diluted in KHS containing 0.02% pluronic F-127 was performed before placing the flow chamber onto the microscope stage and connecting it to a syringe pump (Cetoni, low-pressure module). Next, the flow chambers were flushed for a few minutes at a flow rate of 0.1 ml min⁻¹ (resulting in negligible shear stress of around 0.01 Pa) with KHS that was preheated to 29 °C and degassed to 3% O₂ using a gas mixer. Appropriate flow rates resulting in specific shear stresses on the cell substrate were calculated using established formulas of fluid flow in rectangular channels. During shear-stress experiments, image stacks (5 × 3 μm) were acquired using the Imaris widefield microscope (×10 objective) at a frequency of 1 Hz, a wavelength of 488 nm and an exposure time of 100 ms.

Image analysis was performed using an initial average intensity z projection of the image stacks, followed by a segmentation of individual cell bodies performed with a custom ImageJ script based on the fluorescence at the baseline, that is, a 30 s interval before application of the shear-stress stimulus (Supplementary Fig. 3). The mean fluorescence intensity for each individual cell was then calculated and normalized to the average intensity measured at the baseline. A Ca²⁺ signal in a cell was defined as such when the normalized fluorescence intensity ($ΔF/F$) exceeded the baseline fluorescence intensity by 10× the s.d. of the baseline during a 20 s interval after exposure to shear stress.

### Generation of CRISPR-Cas9-mediated knockdown cells

Single-guide RNAs (sgRNAs) against multiple candidate genes were designed using the CRISPRDirect online tool (http://crispr.dbscl.jp)⁹. Only highly specific target sites were selected; a list of the respective sequences is provided in Supplementary Table 1. A non-targeting control sgRNA was selected and checked for low targeting potential using a BLASTN 2.8.0 search. Target sequence oligos were synthesized with BsmBI restriction site overhangs by Microsynth and then annealed and cloned into the lentivirus CRISPR2 transfer plasmid, a gift from E. Zhang (Addgene plasmid, 52961)⁹, according to the protocol provided by the Feng Zhang Lab.

Lentiviral particles were produced by cotransfection of the lentivirus CRISPR2 plasmid, containing the respective gRNA sequence, with the packaging plasmids pCMV- SVSV-G (a gift from B. Weinberg; Addgene plasmid, 8451)⁹ and pPAX2 (a gift from D. Trono; Addgene plasmid, 12260) into HEK293T cells using Lipofectamine 3000 (Thermo Fisher Scientific, L3000008), according to the manufacturer's instructions.

For transduction, human and rat tenocytes were incubated for 24 h with supernatant containing the viral particles and supplemented with 8% (v/v) polybrene. Subsequently, human and rat cells were selected with 3 μg/ml puromycin (Gibco, A1113803) for 3 d or with 4 μg/ml deionized water and air dried⁶. Finally, a block of PDMS containing a canal (height, 0.4 mm; width, 5 mm; length, 30 mm) was glued on top of the microscope slide, centring the microgrooved path in the middle of the canal. A fine layer of PDMS containing additional 0.1% platinum-divinyltetramethyldisiloxane (abcr, 146697) was used as glue and cured at 45°C for 2 h.

### Immunofluorescence

Cells seeded in flow chambers were fixed with 4% formaldehyde in PBS (Carl Roth, 3105.2) for 20 min at room temperature and subsequently permeabilized with 0.1% Triton X-100 (Axygen, 10029070) and 0.5% bovine albumin serum (RSA, VWB P6154) in PBS for 10 min. Samples were incubated with specific primary antibodies in PBS with 3% BSA for 1 h and subsequently with a secondary fluorescently labelled antibody. Between every step, samples were washed three times with PBS. Primary antibodies were used against PIEZO1 (Novus Biologicals NB1P-78486 for (human cells), 1:25; Alomone Labs APC-087 (for rat cells), 1:3000). Actin filaments were stained with Alexa Fluor 568 phalloidin (Thermo Fisher Scientific, A12380, 1:200) and cell nuclei with NucBlue (Thermo Fisher Scientific, R37605). Alexa-Fluor-488-conjugated donkey anti-rabbit (Thermo Fisher Scientific, A-21206, 1:100) was used as a secondary antibody. Immunofluorescence images were acquired using the Micro spinning disk confocal microscope using a x60/1.35 NA oil-immersion objective.

### Western blot analysis

Cells were washed with PBS and lysed directly in the cell culture dish with 80 μl of 1x reduced Laemmli buffer (Thermo Fisher Scientific, 15493939) and boiled for 3 min at 95°C. Next, 15 μl of each sample was loaded onto a 4–15% Mini-PROTEAN TGX stain-free protein gel (Bio-Rad, 4568086). Total protein was analysed using the Sypro Ruby staining kit (Bio-Rad, 1610714) and transferred onto polyvinylidenefluoride membranes using the Trans-Blot Turbo System (Bio-Rad). Membrane blocking was performed with 5% non-fat dry milk/TBS-T for 1 h at room temperature. The primary antibodies targeting PIEZO1 (Thermo Fisher Scientific, MA5-32676, 1:300) and β-tubulin (Abcam, ab80314, 1:100000) were normalised to GAPDH and incubated overnight at 4°C. Next, the membranes were washed three times in TBS-T and incubated with the secondary antibody (anti-mouse, Sigma-Aldrich, SASB370137, 1:20,000) for 1 h at room temperature. Images were taken using Ultra Silver Super Ultra Wideband Substrate (GeneDireX, CCH345-B) and the ChemiDoc MP imaging system (Bio-Rad).

### Tenocyte-targeted Piezo1 knockout mouse

Scc-creERT2; Piezo1+/- mice were generated by crossing Scc-creERT2 mice (provided A. Huang, Ichthy School of Medicine at Mount Sinai) with Piezo1+/-mice (Piezo1+/-mice; Jackson Laboratory, 029213) to create tamoxifen-inducible tendon-targeted Piezo1-knockout mice. For the experiments (approved by the Veterinary Office of the Canton of Zurich, ZH104/2018), male Scc-creERT2; Piezo1+/- mice were mated with female Piezo1+/- mice. Tamoxifen (Sigma-Aldrich, T5648) in corn oil was given to pups by intragastic injections at P1 (0.05 mg tamoxifen), P2 (0.05 mg) and P3 (0.1 mg). Wild-type littermates (lacking Cre) were used as controls. For gene expression analysis (verification of knockout levels) and Ca²⁺-imaging experiments, tissues were isolated from the tails shortly after euthanising the mice. For biomechanical testing of fascicles, tails were stored at -20°C after euthanising the mice.

### Tendon explants cultured in bioreactor and subjected to recurrent sham or Yoda1 stimulation

Tendon explants were freshly isolated from female Wistar rats (aged 14–18 weeks) and placed into culture medium (high-glucose Dulbecco’s modified Eagle’s medium (Sigma-Aldrich, D6429, supplemented with 1% penicillin–streptomycin), 200μg ascorbic acid (Wako Chemicals 013–9641) and 1% N-2 supplement (Thermo Fisher Scientific, 7001585)). Each fascicle was cut into half and was used for mechanical testing and day 0, while the other half was cultured in our custom-made bioreactor at the preload (crimp disappearance, that is, minimal mechanical load) and mechanically tested at day 16. Distal and proximal samples were randomly distributed between the 2 d. Distal samples were mechanically tested (day 0, 12 after isolation). After the 30 min treatment, fascicles were washed once with medium, then resuspended in medium and incubated at 29°C under 5% CO₂ and 3% O₂. Ramp-to-failure experiments were performed to assess the biomechanical properties. Samples were preloaded to 0.04 N and preconditioned 5 times to 1% strain. Subsequently, a ramp-to-failure waveform was applied at 1% strain per s. Fascicle stiffness was calculated in the linear region of the force–strain curves and fascicle strength was determined from the maximal force.

### Gene expression analysis of fascicles stimulated mechanically or pharmacologically

Rat tail tendon fascicles were freshly extracted from female Wistar rats (aged 14–18 weeks) and placed in the culture medium described above. For the experiment with pharmacological stimulation, fascicles were cultured free-floating and were stimulated with a sham control or a 5μM Yoda1 (Sigma-Aldrich, SML1558-5MG) stimulation for 30 min on days 0, 3, 6, 9 and 12 after isolation. After the 30 min treatment, fascicles were washed once with medium, then resuspended in medium and incubated at 29°C under 5% CO₂ and 3% O₂. Ramp-to-failure experiments were performed to assess the biomechanical properties. Samples were preloaded to 0.04 N and preconditioned 5 times to 1% strain. Subsequently, a ramp-to-failure waveform was applied at 1% strain per s. Fascicle stiffness was calculated in the linear region of the force–strain curves and fascicle strength was determined from the maximal force.

For gene expression analysis, fascicles were cultured free-floating and treated with a sham control or a 5μM Yoda1 (Sigma-Aldrich, SML1558-5MG) for a period of 30 min. For the experiment with mechanical stimulation, fascicles were cultured in our定制的生物反应器中刺激四次，每次刺激持续1%应变，共30分钟。实验后，测量了机械性能，发现应变敏感性在每个刺激的应变曲线中，应变曲线的斜率和应变曲线的面积随刺激次数而增加。
Biomechanical testing and analysis. The biomechanical properties of tail tendon fascicles and plantaris tendons from female and male Piezo1lox/lox mice, Piezo1lox/lox mice and the corresponding wild-type littermates were investigated with ramp-to-failure experiments. Mice were euthanized and stored at either −20 °C or −80 °C until the day of the experiment (approval by the Institutional Animal Care and Use Committees of Scripps Research in accordance with the guidelines established by the Association for Assessment and Accreditation of Laboratory Animal Care International, and approval by the Veterinary Office of the Canton of Zurich, ZH/104/2018). After thawing, tail tendon fascicles (from 20–39-week-old Piezo1lox/lox mice, and from 10–13-week-old Piezo1lox/lox mice) and plantaris tendons (from 20–21-week-old Piezo1lox/lox mice) were carefully isolated and tested in uniaxial tension using a custom clamping technique on a universal testing machine that recorded force–displacement data (Zwick 2010 TN, 20 N load-cell). During testing, tendons were kept in a chamber filled with KHS, preloaded to 0.025 N (tail tendon fascicles) or to 0.1 N (plantaris tendons) that corresponds to the initial length L0 (that is, 0% strain) and preconditioned five times to 1% strain (preload reapplied after every cycle). Subsequently, samples were ramped to failure at a constant strain rate of 1% strain per s. The diameter was measured on the basis of microscopic images of the tail tendon fascicles (x20 objective, Motic, AE2000) and the plantaris tendons (x5 objective, Nikon, Eclipse E200). Tendon stiffness was calculated in the linear region of the force–strain curves and tendon strength was determined from the maximal force.

Two-photon microscopy for assessing cross-link-associated fluorescence. Achilles tendons were isolated from mice (agged 19–39 weeks) that were euthanized and stored at −80 °C. Samples were mounted between a microscopy slide and a cover slide with a drop of PBS. Images were acquired with an upright Leica TCS SP8 MP DIVE FALCON two-photon microscope, equipped with a tunable (680–1,300 nm) 80 MHz laser and four spectrally tunable non-descanned photon-counting hybrid detectors. A x63/1.2 NA water-immersion objective was used. Collagen cross-links associated with the collagen cross-link pyridinoline and deoxy-pyridinoline were analysed with 720 nm excitation and 380–425 nm emission; second-harmonic-generation signal associated with the collagen content was investigated with 880 nm excitation and 430–450 nm emission. Laser power ranged from 25 mW to 35 mW. 2 stacks were acquired starting from the tendon surface with 5 planes at 4 μm increments. For each sample, 2 stacks were acquired at 4 different locations. Image analysis was performed by averaging the intensity signal over the five planes and the four locations and by calculating the ratio between the averaged cross-links-associated signal and the averaged SHG signal.

Differential scanning calorimetry measurements. Achilles tendons were thawed and placed in PBS for 10 min. After light blotting the sample (that is, a single Achilles tendon) on a paper towel to remove excessive PBS, it was placed in a stainless-steel pan that was sealed with a press. The heat flow was recorded with a differential scanning calorimeter (DSC 2920, TA Instruments) during the following protocol: constant heating rate of 5 °C/min from 25 °C to 45 °C, followed by a heating rate of 2 °C/min from 45 °C to 70 °C. An empty pan was used as a reference. The denaturation temperature was determined as the temperature at the peak heat flow. The area of the denaturation curve was calculated by subtracting the heat flow baseline from the heat flow curve (Fig. 6d).

Transmission electron microscopy imaging. Plantaris tendons were freshly isolated from littermates (aged 29–34 weeks) that were euthanized in the middle of the day (normal light–dark cycle) and sequentially fixed with 2.5% glutaraldehyde (Sigma–Aldrich, G5882) in 0.1 M sodium cacodylate buffer (pH 7.2), with 1% OsO4, in 0.1 M sodium cacodylate buffer at room temperature and with 1% uranyl acetate in H2O at room temperature for at least 1 h per step. Samples were used for scanning transmission electron microscopy (STEM) imaging. Collagen fibrils were prepared using the Trainable Weka Segmentation Fiji plugin.

Activity level and sports participation of the human participants. Healthy self-reported African-American participants (at least 18 years old) were enrolled after approval by the Institutional Review Board of the University of Delaware and written informed consent. A clinical evaluation with ultrasound imaging was performed to ensure that the individuals had no underlying pathologies in their Achilles tendons. Furthermore, the Victorian Institute for Sports Assessment—Achilles questionnaire (VISIA-A) was used to confirm that the Achilles tendons were healthy. Participants reported their highest level of sports participation (recreational, second level, collegial or professional) and their history of sports participation. The Physical Activity Scale was used to assess the individual’s reported current physical activity level.

Ultrasound-based assessment of the human Achilles tendon morphology. B-mode ultrasound imaging (LOGIQ e ultrasound system (GE Healthcare) with wide-band linear array probe (5.0–13.0 MHz)) was used to analyse the Achilles tendon morphology. In brief, the Achilles tendon cross-sectional area was measured at a distance of 2.5 cm from the calcaneal osteotendinous junction (axial direction) in the images acquired parallel and perpendicular to the fibre orientation (each three repetitions, respectively). Achilles tendon length was measured as the distance from the calcaneal osteotendinous junction to the myotendinous junction of the gastrocnemius and soleus muscles using an extended field of view. The software OsiriX MD (Pixmeo) was used to analyse the ultrasound images.

Functional performance tests. To investigate the jump heights, we used the MuscleLab (Ergotest Innovation) light mat measurement system, which creates an infrared light field 4 mm above the floor and records beam interruptions. The height and weight of participants were recorded before the jumping tests. Jump height was calculated using MuscleLab using the participant weight, ground contact time and flight time. Participants performed two different jump tests. In each test, the participants were asked to place their hands behind their back and to jump as high as possible. The first test was a single leg CMJ in which the participants started by standing on the floor on one leg then quickly bent the knee before jumping straight up as high as possible. This was repeated three times with each leg. The second test was a single leg DC MJ, in which participants jumped off of a 20 cm high box and then jumped vertically as high as possible. For each leg, the average height of three trials was used for analysis.

Genotyping of the human PIEZO1 (E756del) mutation. Saliva samples were collected using Oragene DNA collection kits (OG-500, DNA Genotek). Isolation of genomic DNA was performed according to the manufacturer’s instructions using the prepIT-L2P reagent (PT-L2P, DNA Genotek) included in the kit. The region containing the E756 locus was amplified using PCR (forward primer 5′-CAGGCAAGTGCAGTGATG-3′ and reverse primer 5′-GGCACAGGCCAGAGCAG-3′). This amplicon (around 200 bp) was sequenced using both primers to identify non-carriers and E756del carriers.

Statistical analysis. For multiple comparisons, data were analysed using one-way analysis of variance (ANOVA; Tukey or Dunnnett test). Intergroup comparisons were performed using two-tailed Student’s t-tests or two-tailed Mann–Whitney U-tests. For mouse and human data, n represents the number of animals or participants; at least n = 4 was used. Datasets that included the investigation of more than one tendon from the same animal (for example, multiple tendon fascicles from the same tail, or left and right plantaris) or from the same participant (for example, left and right Achilles tendons) were analysed with linear mixed-effects models (lmer package in R). For mouse data, the mouse ID was defined as random effect and litter as a fixed effect. For human data, the individual ID was defined as a random effect and leg as a fixed effect. The age, height, weight, highest level of sports participation and activity level of the participants were tested as covariates. In the figures, data are mean ± s.e.m. unless indicated otherwise. Analyses were performed using GraphPad Prism v.8.2 and v.9.0 or RStudio v.1.1.383.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability
The main data supporting the findings of this study are available within the paper and its Supplementary Information. The raw and analysed datasets generated during the study are too large to be publicly shared, yet they are available from the corresponding author on reasonable request.

Code availability
The software of the stretching device, as well as MATLAB, Image J and R codes, are all available from the corresponding author on request. The toolbox CHIPS is freely available.

Received: 16 July 2020; Accepted: 17 March 2021; Published online: 24 May 2021.

Acknowledgements
We thank A. Ziegler for software assistance; N. Wili for support in chemistry; B. Rutishauser and E. Bachmann for engineering assistance; L. Gasser (Statistical Consulting Group, ETH Zurich) for statistical support; members of the Sneadker group for constructive discussions; A. Huang and R. Schweitzer for providing Scx-creERT2 mice; A. Patapoutian for providing Piezo1+/− mice and feedback; U. Lieth and A. Käch from the Center for Microscopy and Image Analysis (University of Zurich) for help with transmission electron microscopy; R. Mezzenga and Y. Yao (ETH Zurich) for access to the differential scanning calorimeter and assistance during the experiments; and P. Aagaard for insights on the human jumping performance data. Funding was provided by the Swiss National Science Foundation (grant numbers 165670 and 185095).

Author contributions
F.S.P., P.K.J., A.S.S. and J.G.S. designed experiments and wrote the manuscript. F.S.P. performed the Ca2+ imaging experiments with tendon explants. F.S.P., K.D.E., D.H., S.C., A.N.H., U.S. and B.W. designed and analysed the Ca2+ imaging experiments. P.K.J. and F.S.P. carried out and analysed the shear-stress experiments. M.J.A., F.S.P., M.B. and B.P.-T. generated and analysed the knockout cells. S.F.F., M.B. and U.B. helped with human tendon tissues and isolation of primary cells. F.S.P. and S.M. performed mouse experiments. S.H., K.G.S., F.S.P. and J.G.S. designed and performed the human study. F.S.P. and B.P.-T. carried out human genotyping. F.S.P., S.H. and T.G. analysed the human data. All of the authors provided feedback on the manuscript.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our Editorial Policies and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

| n/a | Confirmed |
|-----|-----------|
| ◯   |            |
| ◯   | The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement |
| ◯   | A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly |
| ◯   | The statistical test(s) used AND whether they are one- or two-sided |
|     | *Only common tests should be described solely by name; describe more complex techniques in the Methods section.* |
| ◯   | A description of all covariates tested |
| ◯   | A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons |
| ◯   | A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals) |
| ◯   | For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted |
|     | *Give P values as exact values whenever suitable.* |
| ◯   | For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings |
| ◯   | For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes |
| ◯   | Estimates of effect sizes (e.g. Cohen’s d, Pearson’s r), indicating how they were calculated |

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

**Data collection**

TILL Photonics Live Acquisition, custom-developed software of stretching device implemented in C++ within the QT framework with integrated third-party libraries, Leica Application Suite X, Picoquant Symphotime 64 FLIM, neMESYS (Cetoni), ChemiDoc MP imaging system (Bio-Rad), MAPS (Thermo Fisher Scientific), testXpert II (ZwickRoell), Motic Images Plus 2.0, GE Logio e ultrasound (GE Healthcare), and MuscleLab (Ergotest Innovation).

**Data analysis**

CHIPS (Cellular and Hemodynamic Image Processing Suite), MATLAB R2016a and R2019a, Huygens Professional 18.10 (Scientific Volume Imaging), Imaris 7.7 (Bitplane AG), ImageJ 1.51 and 1.52, Picoquant Symphotime 64 FLIM, RStudio v1.1.383, GraphPad Prism 8.2, OsiriX MD (Pixmeo SARL), and MuscleLab (Ergotest Innovation).

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

The main data supporting the findings of this study are available within the paper and its Supplementary Information. The raw and analysed datasets generated during the study are too large to be publicly shared, yet they are available from the corresponding authors upon reasonable request.
Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

**Sample size**
The sample sizes were determined on the basis of comparable experiments reported in the literature and on the basis of the consistency and magnitude of the measurable changes. The number of participants of the human study was predetermined with a power analysis.

**Data exclusions**
In three participants of the human study, we found an additional mutation (E750Q) very close to the E756del mutation on the same chromosome. These three participants were excluded, due to the unknown consequence of the double mutation on the kinetics of the PIEZO1 channel. No other data were excluded.

**Replication**
We performed multiple independent experiments, as described in the figure legends. The results were reproducible.

**Randomization**
Knockout cells were assigned to the experimental group according to the specific gene that was modified. Mice and human participants were allocated into the experimental groups according to their genotype. For mice, factors such as animal ID, litter and age were included in the analysis. For humans, the following factors were included in the analysis: participant ID, age, weight, height, levels of activity and sports participation.

**Blinding**
During experiments with cells and mice, the investigators were not blinded to group allocation, as data analysis was performed automatically with the same scripts for every experimental group.

During the human study, investigators as well as participants were blinded to group allocation. Genotyping was performed after data collection.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

| Materials & experimental systems | Methods |
|----------------------------------|---------|
| n/a | n/a |
|x| x| Antibodies | Involved in the study |
|x| x| Eukaryotic cell lines | ChIP-seq |
|x| | Palaeontology and archaeology | Flow cytometry |
| | | Animals and other organisms | MRI-based neuroimaging |
| | | Human research participants | |
|x| | Clinical data | |
|x| | Dual use research of concern | |

**Antibodies**

- Rabbit polyclonal anti-human PIEZO1, Novus Biologicals Cat# NBP1-78446, dilution 1:25
- Rabbit polyclonal anti-rat PIEZO1, Alomone Labs Cat# APC-087, dilution 1:300
- Alexa Fluor 488 conjugated donkey polyclonal anti-rabbit IgG, Thermo Fisher Scientific Cat# A-21206, dilution 1:100
- Mouse monoclonal anti-human PIEZO1, Thermo Fisher Scientific Cat# MAB-32876, dilution 1:500
- Mouse monoclonal anti-human Tubulin beta, MERCK Millipore Cat# MAB3408, dilution 1:10'000
- Rabbit polyclonal anti-mouse IgG, Sigma-Aldrich Cat# SAB3701073, dilution 1:20'000

**Validation**
All three anti-PIEZO1 antibodies showed clearly reduced signal in CRISPR-Cas9-mediated Piezo1-knockout cells.

**Eukaryotic cell lines**

Policy information about cell lines

- HEK 293T/17 cells were acquired from the American Type Culture Collection (ATCC).
Authentication
- HEK 293T/17 cells were authenticated by American Type Culture Collection (ATCC).

Mycoplasma contamination
- HEK 293T/17 cells were not tested for mycoplasma contamination.

Commonly misidentified lines
- No commonly misidentified cell lines were used.

### Animals and other organisms

**Policy information about studies involving animals**: ARRIVE guidelines recommended for reporting animal research

**Laboratory animals**
- Rats: Wistar (from Janvier-Labs), females, 14–18 weeks of age, 250–350 g of weight.
- Mice strains:
  - Piezo1GOF mice, in C57BL/6 background, females and males, 20–39 weeks of age, 25–35 g of weight.
  - Piezo1 knockout mice, in C57BL/6 background, females and males, 7–13 weeks of age, 20–30 g of weight.

**Wild animals**
- The study did not involve wild animals.

**Field-collected samples**
- The study did not involve samples collected from the field.

**Ethics oversight**
- Veterinary Authorities of the Canton of Zurich, Institutional Animal Care and Use Committees of Scripps Research.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

### Human research participants

**Policy information about studies involving human research participants**

**Population characteristics**
- Females and males, 18–36 years old, healthy individuals of African descent (African Americans), 22 carrying the E756del allele and 43 carrying the wild-type allele, all with healthy Achilles tendons.

**Recruitment**
- Recruitment flyers were posted in the community, in the University of Delaware physical therapy clinic, and through local referral sources in the area. Results are likely not biased by the recruitment because of the unknown genotype at the time of recruitment. Saliva samples were processed after data collection.

**Ethics oversight**
- Institutional Review Board of the University of Delaware.

Note that full information on the approval of the study protocol must also be provided in the manuscript.
