ABSTRACT

Interactions between dark matter (DM) and radiation (photons or neutrinos) in the early Universe suppress density fluctuations on small mass scales. Here, we perform a thorough analysis of structure formation in the fully non-linear regime using N-body simulations for models with DM–radiation interactions and compare the results to a traditional calculation in which DM only interacts gravitationally. Significant differences arise due to the presence of interactions, in terms of the number of low-mass DM haloes and their properties, such as their spin and density profile. These differences are clearly seen even for haloes more massive than the scale on which density fluctuations are suppressed. We also show that semi-analytical descriptions of the matter distribution in the non-linear regime fail to reproduce our numerical results, emphasizing the challenge of predicting structure formation in models with physics beyond collisionless DM.

Key words: astroparticle physics – galaxies: haloes – dark matter – large-scale structure of Universe.

1 INTRODUCTION

Dark matter (DM) is the most dominant and yet most elusive component of matter in the Universe. Exploring its nature is therefore one of the greatest challenges in both cosmology and particle physics today. The usual treatment of DM in structure formation (SF) calculations neglects possible interactions between DM and other species. Yet if DM is a (thermal) weakly interacting massive particle (WIMP), interactions (and more precisely, annihilations) are essential to obtain the correct relic density. It is therefore important to study the impact of DM interactions on other cosmological observables.

It has been already established that a DM coupling with primordial radiation, i.e. photons (Boehm, Fayet & Schaeffer 2001; Boehm et al. 2002; Sigurdson et al. 2004; Boehm & Schaeffer 2005; Dolgov et al. 2013; Wilkinson, Boehm & Lesgourgues 2014a) or neutrinos (Boehm et al. 2001, 2002; Boehm & Schaeffer 2005; Mangano et al. 2006; Serra et al. 2010; Wilkinson, Boehm & Lesgourgues 2014b) leaves a characteristic imprint on the cosmic microwave background (CMB) temperature and polarization power spectra. In addition, in a previous publication (Boehm et al. 2014), we showed using N-body simulations that such interactions have a significant impact on the Milky Way environment, dramatically reducing the number of DM subhaloes that could potentially host satellite galaxies. Since they have the potential to alleviate the small-scale problems that have persisted in the standard cold DM (CDM) model for more than a decade (Klypin et al. 1999; Moore et al. 1999; Boylan-Kolchin, Bullock & Kaplinghat 2011), these interactions should not be ignored.

We now go a step further and study the abundance and properties, such as shape, spin and density profile of collapsed DM structures in the presence of DM–radiation interactions. We highlight the differences with respect to CDM and in addition, warm DM (WDM), which shows a qualitatively similar suppression of power on small scales (Schaeffer & Silk 1988). We note that recent work has also considered non-linear SF in a number of alternative models such as self-interacting DM (Rocha et al. 2013; Vogelsberger et al. 2014), decaying DM (Wang et al. 2014), late-forming DM (Agarwal et al. 2014), atomic DM (Cyr-Racine & Sigurdson 2013) and DM interacting with dark radiation (Buckley et al. 2014; Chu & Dasgupta 2014); see also Schneider (2014).

The paper is organized as follows. In Section 2, we summarize the theoretical background and results obtained thus far using linear perturbation theory. In Section 3, we describe the setup of our numerical simulations. In Sections 4 and 5, we analyse the abundance and properties of the collapsed structures, comparing our results with semi-analytical approximations from the literature. Our conclusions are presented in Section 6.
mass are given in Table 1. These parameters are motivated by the constraints obtained in our previous work (Boehm et al. 2014) and have been selected such that the scale at which the transfer function is suppressed by a factor of 2 with respect to CDM (hence giving a factor of 4 reduction in power) is identical. This scale defines the half-mode mass, $M_{\text{hm}}$, and marks the range of wavenumbers labelled as regions I and II in Fig. 1. In region II, there are important differences between the power spectra for $\gamma$CDM, $\nu$CDM and WDM.

In the case of a thermalized, non-interacting, fermionic WDM particle, the suppression in the matter power spectrum is typically approximated by the transfer function (Bode, Ostriker & Turok 2001)

$$T(k) = \left[ 1 + (\alpha k)^2 \right]^{-\frac{5}{\mu}}, \quad (1)$$

where

$$\alpha = 0.048 \left[ \frac{m_{\text{DM}}}{\text{GeV}} \right]^{-1.15} \left[ \frac{\Omega_{\text{DM}}}{0.4} \right]^{0.15} \left[ \frac{h}{0.65} \right]^{1.3} \frac{\text{Mpc}}{h}. \quad (2)$$

Here, $\Omega_{\text{DM}}$ is the DM energy density, $h$ is the reduced Hubble parameter and $\mu \approx 1.2$ is a fitting parameter. The scale $\alpha$ in equation (2) encapsulates the effect of free-streaming, which erases primordial fluctuations below a wavelength given by

$$\lambda_{\text{fs}} = \int_{t_{\text{EQ}}}^{t_{\text{dec}}} \frac{\nu(t)}{a(t)} \, dt \approx r_H(t_{\text{EQ}}) \left[ 1 + \frac{1}{2} \log \left( \frac{t_{\text{dec}}}{t_{\text{EQ}}} \right) \right], \quad (3)$$

where $\nu(t)$ is the thermal velocity of the WDM particle. In this expression, $t_{\text{dec}}$ is the DM decoupling time, $t_0$ is the time today, $a(t)$ is the cosmological scalefactor, $r_H(t_{\text{EQ}})$ is the comoving size of the horizon when DM becomes non-relativistic (at time $t_{\text{EQ}}$) and $t_{\text{EQ}}$ is the epoch of matter-radiation equality.

A similar transfer function can be used to model the cut-off in the matter power spectra in $\gamma$CDM and $\nu$CDM (Boehm et al. 2002) with

$$\tilde{a} = \beta_X \left[ \frac{\sigma_{\text{DM},X}}{\sigma_{\text{Th}}} \right] \left[ \frac{m_{\text{DM}}}{\text{GeV}} \right]^{0.48} \left[ \frac{\Omega_{\text{DM}}}{0.4} \right]^{0.15} \left[ \frac{h}{0.65} \right]^{1.3} \frac{\text{Mpc}}{h}, \quad (4)$$

where $X$ is $\gamma$ or $\nu$, $\beta_x \approx 1.25 \times 10^3$, $\beta_y \approx 1.04 \times 10^4$, $\sigma_{\text{DM},X}$ is the DM–radiation cross-section and $\sigma_{\text{Th}}$ is the Thomson cross-section. This transfer function fixes the half-mode scale for $\gamma$CDM and $\nu$CDM, thus providing a means to compare the impact of the interactions with respect to WDM, but does not encapsulate the full suppression of the power spectrum.

2 In addition, $\gamma$CDM has a direct impact on the CMB, while $\nu$CDM only affects the CMB indirectly, and the parameter space for $\nu$CDM suffers from significant degeneracies (see Wilkinson et al. 2014b).

3 There is an alternative fit for $\alpha$ and $\mu$ that is often used in the literature (e.g. Viel et al. 2005), but the difference is marginal for our analysis.
Equation (4) corresponds to an analytical calculation of the collisional damping scale given by

$$\lambda_{cd} = \frac{2\pi^2}{3} \left[ \frac{\rho_X v_X^2}{a^2} \left( 1 + \Theta_X \right) \right] \frac{\Gamma_X}{\Theta_X} dt.$$  

(5)

In this equation, $\rho_X = \rho_X + \rho_Y$, where $\rho_X$ is the energy density, $\rho_Y$ the pressure, $v_X$ the velocity dispersion and $\Gamma_X$ is the total interaction rate of the DM interaction partner and $\Theta_X$ contains the contribution from heat conduction.

As the integral in equation (5) is dominated by the contribution at late times, the collisional damping scale can be approximated by

$$\lambda_{cd} \approx \frac{2\pi^2}{3} \left[ \frac{\rho_X v_X^2}{a^2} \left( 1 + \Theta_X \right) \right] \frac{\Gamma_X}{\Theta_X} t_{dec},$$  

(6)

using $\Gamma_X = H = \alpha_X / t$ at $t = t_{dec}$, where $H$ is the Hubble rate, $\alpha_X = 1/2$ if $t_{dec} < h_{100}$ and $\alpha_X = 2/3$ otherwise. On scales smaller than $\lambda_{cd}$, primordial fluctuations are erased.

We summarize the impact of the damping scales $\lambda_{fs}$ and $\lambda_{cd}$ in linear theory in Fig. 2. To distinguish these quantities from the half-mode mass scale, $M_{\text{hm}}$, we present the mass corresponding to the relevant damping scale as a function of the DM mass (for WDM) and interaction cross-section (for $\gamma$CDM and $\nu$CDM).

We identify three regions in Fig. 2. Regions I and II are already labelled in Fig. 1 and there is now an additional region (III) occurring at much higher wavenumbers than that are plotted in this figure. In region I, haloes form hierarchically, while in region III, all primordial perturbations have been erased. In between lies a transition region (region II), where some primordial density fluctuations may survive to form structure, but these are already sufficiently suppressed to disfavour a typical hierarchical SF. Region II extends down to much smaller scales for $\gamma$CDM and $\nu$CDM compared to WDM due to the prominent oscillations in the matter power spectrum. The separation between regions I and II is determined by the half-mode mass scale (as in Fig. 1), while the transition between regions II and III is governed by the free-streaming scale (for WDM) or collisional damping scale (for $\gamma$CDM and $\nu$CDM).

### 3 SIMULATIONS

To calculate the non-linear evolution of the matter distribution, we run a suite of high-resolution $N$-body simulations using the parallel Tree-Particle Mesh code, GADGET-3 (Springel 2005). To model a wide dynamical range, we perform simulations in large boxes (of side lengths 100 and 300 $h^{-1}$ Mpc) and a small box (of side length 30 $h^{-1}$ Mpc), all containing 1024$^3$ particles.

The simulations begin at a redshift of $z = 49$ (the DM–radiation interaction rate is negligible for $z < 49$) and use a gravitational softening of 5 per cent of the mean particle separation. The initial conditions are created with an adapted version of a second-order LPT code (Crocce, Pueblas & Scocciarino 2012), using input matter power spectra from a modified version of the Boltzmann code, CLASS (Lesgourgues 2011).

Figure 2. Characteristic mass scales for the suppression of primordial fluctuations by free-streaming (WDM, top), photon collisional damping ($\gamma$CDM, middle) and neutrino collisional damping ($\nu$CDM, bottom). The half-mode mass scale, $M_{\text{hm}}$, is defined by the initial cut-off in the transfer function and marks the upper boundary of region II, where hierarchical SF may no longer occur due to a reduced number of low-mass progenitors. $M_{\text{fs}}$ and $M_{\text{cd}}$ are the masses corresponding to the free-streaming and collisional damping scales, respectively, and define the boundary of region III, where structures no longer form. The colour scale shows the absolute value of the transfer function, $T(k)$, and the vertical red lines correspond to the DM parameters listed in Table 1.

---

4 We neglect the possible contributions from self-interactions and mixed damping and simplify the calculation to a single DM interaction partner.

5 We note that acoustic oscillations are also expected in the transfer functions for certain WDM models at small scales (see e.g. Boyanovsky & Wu 2011). However, at these scales, the transfer function is already strongly suppressed by free-streaming so the regeneration of power from these oscillations is expected to be much weaker than in $\gamma$CDM and $\nu$CDM.
We use the best-fitting values of the cosmological parameters obtained by the Planck collaboration in the ‘Planck + WP’ data set (Planck Collaboration XVI 2014), assuming a flat ΛCDM cosmology. In principle, a consistent treatment of an interacting DM model would require one to study each cross-section within its own best-fitting cosmology. However, we find that the parameters for ΛCDM lie within one standard deviation of such best fits. Therefore, we keep the cosmological parameters fixed for all the models studied here.

Lovell et al. (2014) showed that in the case of WDM, one can safely ignore thermal velocities, without introducing a significant error on the scales of interest, if the DM particle is heavier than ~1 keV. We confirmed this by performing simulations with and without a thermal velocity dispersion and obtaining convergence on the scales of interest. Hence, we only consider models in which late-time free-streaming can be neglected.

Fig. 3 shows the projected DM distribution in the 30 h⁻¹ Mpc box for (i) collisionless CDM and (ii) an extreme γCDM model that is allowed by Planck CMB data (Wilkinson et al. 2014a). Fewer small structures are present in γCDM as an immediate result of the suppression of small-scale power shown in Fig. 1. The only exception is found along the filaments, where spurious structures contaminate the otherwise smooth environment (Wang & White 2007). Similar results are obtained for γCDM and WDM.

For abundance measurements (Section 4), DM haloes are identified using a friends-of-friends group finder (Davis et al. 1985) with a linking length of 20 per cent of the mean particle separation. For the halo properties (Section 5), we instead use the AMIGA halo finder (Knollmann & Knebe 2009), where collapsed structures are defined as spherically overdense regions of radius rvir with a mean density given by

\[ \frac{3M_{\text{vir}}}{4\pi r_{\text{vir}}^3} = \Delta_{\text{th}}\rho_{\text{crit}}. \]  

(7)

In this expression, Mvir is the virial mass, ρcrit is the critical density and Δth is the mean overdensity of a virialized halo with respect to the critical density, according to the spherical top-hat collapse model.

4 RESULTS: HALO ABUNDANCE

The suppression of small-scale density fluctuations in the early Universe (as discussed in Section 2) has a significant effect on the subsequent SF. This has been studied in detail for WDM (e.g. Lovell et al. 2014), where the halo mass function (HMF) was compared to semi-analytical predictions. In this section, we perform a similar analysis for γCDM and vCDM by comparing the simulated HMFs with the Press–Schechter formalism (Press & Schechter 1974) and modifications thereof. In addition, we study the spatial distribution of DM haloes on large scales.

4.1 Semi-analytical HMFs

The Press–Schechter formalism uses the known primordial perturbations and their linear growth to calculate the fractional volume of space occupied by virialized objects of a given mass, assuming a spherical collapse model (Press & Schechter 1974). The HMF can be written as

\[ \frac{dn(M)}{dM} = \frac{1}{2} f_{\text{HMF}}(\sigma^2) \frac{\dot{\rho}}{\rho} \frac{d\ln \sigma^2(M)}{M^2} \frac{d\ln M}{M}. \]  

(8)

where n(M) is the number density of DM haloes of mass M → M + dM, \( \dot{\rho} \) is the average matter density of the Universe and \( \sigma^2(M) \) is the variance of the linear density field given by

\[ \sigma^2(M) = \frac{1}{2\pi} \int_0^\infty k^2 P(k) \tilde{W}^2(k, R) dk. \]  

(9)

The variance is smoothed on a mass-dependent scale R(M), using a suitable window function W(r, R), which has a Fourier transform \( \tilde{W}(k, R) \) (Jenkins et al. 2001).

The Sheth–Tormen (ST) formalism (Sheth, Mo & Tormen 2001) combines the Press–Schechter formalism with an ellipsoidal collapse model. In this model, the function \( f_{\text{HMF}}(\sigma^2) \) in equation (8) represents the fraction of collapsed haloes and is defined by

\[ f_{\text{ST}}(\sigma^2) = A \sqrt{\frac{2}{\pi}} \left[ 1 + x^{-2p} \right] x \exp \left[ -x^2/2 \right]. \]  

(10)

In this expression, x ≡ \( \sqrt{\Delta \delta_c/\sigma} \), where \( \delta_c \) is the cosmology-dependent linear overdensity at the time of collapse. The parameters A ≈ 0.3222, p ≈ 0.3 and a ≈ 0.707 were obtained by fitting to simulation results (Sheth et al. 2001).

The window function, W(r, R), is in general, arbitrary. However, certain choices of window function are advantageous as they allow for both a sensible definition of the smoothed density field and an semi-analytical solution for the Fourier transform. A real-space topper, W(r, R) = \( \Theta(1 - |r/R|) \), has the advantage of a well-defined smoothing scale, R, defined in terms of the halo mass, M( R ), as

\[ R = \left( \frac{3M}{4\pi\rho} \right)^{1/3}. \]  

(11)

However, recent papers (Benson et al. 2013; Schneider, Smith & Reed 2013) have shown that this choice does not reproduce the HMF for cosmologies with a cut-off in the matter power spectrum at small scales. Instead, the predicted HMF continues to increase with decreasing M, while the suppression of primordial matter perturbations demands the opposite. The reason for this behaviour is illustrated in Fig. 4, where the Fourier-transformed real-space top-hat and (intermediate) steps of the HMF calculations are shown by red/dashed lines. For this type of window function, one obtains significant contributions from a wide range of unsuppressed larger scales, which dominate the resulting variance and thus, the predicted HMF.

A k-space top-hat window function is only sensitive to local changes in the matter distribution in k-space and thus reproduces the expected suppression in the halo abundance for damped power spectra (see Fig. 4, blue/solid lines). However, the mass-smoothing scale relation (M – R) must now be defined without the simple geometrical justification of equation (11), which was used in the real-space case.

Here, we use the definition of Lacey & Cole (1993), which defines the cut-off wavenumber, \( k_s \), in relation to the mass, M, based on the normalization choice

\[ k_s = \left( \frac{M}{6\pi^2 \rho} \right)^{-1/3}. \]  

(12)

This corresponds to a correction factor of c ≡ Rk_s ≈ 2.42 with respect to equation (11), so that the semi-analytical HMF matches numerical simulations at large scales.\(^6\)

\(^6\)Note that Schneider et al. (2013) and Benson et al. (2013) follow a very similar approach, but with slightly different values for c.
Figure 3. The simulated distribution of DM at redshift $z = 0$ in a box of side length $30\, h^{-1}\, \text{Mpc}$ for two models: collisionless CDM (left) and $\gamma$CDM with $\sigma_{\text{DM}} = 10^{-7}\sigma_{\text{Th}}$ (GeV, right), which is allowed by Planck CMB data (Wilkinson et al. 2014a). The colours indicate the DM density on a scale increasing from blue to red. Due to collisional damping, we obtain fewer small-scale structures in $\gamma$CDM than are seen in CDM.

Figure 4. Real-space and $k$-space top-hat window functions in Press–Schechter HMF predictions for $\gamma$CDM. The upper panel shows the matter power spectrum, while the second panel shows the Fourier transform of the two window functions ($r$ top-hat and $k$ top-hat). Each window function is evaluated for two filter masses, $M$ and $M + \Delta M$. The difference between the two filter masses is highlighted by the shaded region in each case. The third panel shows the result of applying this differential filter to the matter distribution. Finally, the lower panel shows the integrated result for both window functions. The red and blue points are the results for the specific filter mass $M$ used in the middle two panels.

Alternatively, Schneider et al. (2012) found that while the $r$-space top-hat did not match the results of their $N$-body simulations, an additional mass-dependent correction factor,

$$\frac{n(M)}{n^\text{ST}(M)} = \left(1 + \frac{M_{\text{hm}}}{\beta M}\right)^{-\alpha},$$

(13)

could correct for this, where $\alpha$ and $\beta$ are free parameters. Schneider et al. (2012) set $\beta = 1$ and found a best-fitting value of $\alpha = 0.6$. As discussed in the next section, we find better agreement with our simulation results by setting $\beta = 2$; we will refer to this version of equation (13) as the modified Schneider et al. correction.

4.2 Simulated HMF

We plot the differential HMFs measured in the collisionless CDM, $\gamma$CDM, $\nu$CDM and WDM simulations in Fig. 5. We also show the predictions obtained using the semi-analytical approximations described in Section 4.1.

The mass function proposed by Schneider et al. (2012) predicts fewer haloes than are seen in collisionless CDM but nevertheless overestimates the abundance of haloes less massive than $\sim 10^{10.5}\, h^{-1}\, \text{M}_\odot$. Using a modified version of the Schneider et al. correction, with $\beta = 2$ instead of $\beta = 1$ extends the reproduction of the simulation results down to a halo mass of $\sim 10^{8.6}\, h^{-1}\, \text{M}_\odot$ for WDM. However, it does not reproduce the abundance of haloes seen in the simulations of $\gamma$CDM and $\nu$CDM, underestimating the measured abundance of haloes at $10^{8.6}\, h^{-1}\, \text{M}_\odot$ by a factor of 2.

The clear upturn observed in the HMF at low masses in Fig. 5 (i.e. below $M_{\text{vir}} \lesssim 10^8\, h^{-1}\, \text{M}_\odot$) is due to non-physical, spurious structures (Wang & White 2007). We try to avoid contamination from such artificial structures by only considering the mass function and halo properties for objects with masses far above this value.

A comparison between the simulated abundance of haloes in the four models and the semi-analytical predictions reveals significant
differences. The main feature, the reduced number of haloes in γCDM, νCDM and WDM, with respect to CDM, is a consequence of the damping of primordial fluctuations on small scales. There is also a larger number of low-mass structures in γCDM and νCDM, relative to WDM, due to the prominent oscillations in the power spectra of the former models, at wavenumbers larger than the scales on which fluctuations are suppressed.

A direct comparison between the γCDM and WDM models (see Fig. 6) reveals that in both cases, the suppression of the HMF follows a universal profile, if the halo mass is plotted normalized by the half-mode mass, $M_{\text{hm}}$. An excess of haloes in γCDM with respect to WDM occurs at $M_{\text{hm}}$ for all the cross-sections studied in this work. A similar result is found for νCDM.

The higher halo abundance seen in the γCDM and νCDM simulations compared to that found in WDM is difficult to explain since the primordial matter power spectra shown in Fig. 1 are very similar down to the wavenumber corresponding to the half-mode mass, $M_{\text{hm}}$. There is a much stronger suppression in the γCDM and νCDM spectra than in WDM immediately below $M_{\text{hm}}$. The scales where the power in γCDM and νCDM exceeds that in WDM correspond to halo masses that are an order of magnitude smaller than $M_{\text{hm}}$, marked by the location of the first oscillation in the halo abundance for γCDM and νCDM, according to the ST formalism. Instead of showing a strong reduction in halo abundance below $M_{\text{hm}}$, the simulated HMFs for γCDM and νCDM seem to bridge the gap between the primary power cut-off scale and the subsequent increase in the halo abundance resulting from the oscillating matter power spectra.

Given that the simulations for WDM, γCDM and νCDM use similar initial conditions (e.g. identical box size, phases, number of particles), numerical errors can most likely be excluded as a possible explanation for this deviation. Therefore, this is a strong hint that the understanding of SF in the ST formalism, which works so well in the strictly hierarchical case, appears to fail when there is oscillating power in the initial matter distribution.

### 4.3 Halo bias

We determine the linear clustering bias of DM haloes, $b_{\text{lin}}(M)$, using the ratio between the halo-density cross-correlation and the density-density autocorrelation on large scales (i.e. at small wavenumbers),

$$b_{\text{lin}}(M) = \lim_{k \to 0} \frac{P_{\text{hm}}(M)}{P_{\text{mm}}}.$$  

Using the cross-correlation of haloes and mass rather than the autocorrelation of haloes reduces the impact of shot noise (see Angulo, Baugh & Lacey 2008).

To ensure that we recover the asymptotic value of $b_{\text{lin}}(M)$, we use the largest simulation box of side length 300 $h^{-1}$ Mpc. For large scales ($k \lesssim 0.1 h^{-1}$ Mpc), convergence is reached as the halo bias becomes constant. Therefore, we can replace the limit in equation (14) with the average over all scales larger than $k = 0.1 h^{-1}$ Mpc to reduce the impact of statistical fluctuations arising from the small number of high-mass haloes and low-wavenumber modes in the simulation box. This wavenumber scale corresponds to the largest mode in the 100 $h^{-1}$ Mpc box and, as the shot noise fluctuations are less important for the more abundant low-mass DM haloes, we use the smaller box to measure the halo bias for masses below $10^{11} h^{-1} M_{\odot}$.

We do not find a significant deviation from the bias expected in collisionless CDM for WDM, γCDM or νCDM, which agrees with the expectations from the semi-analytical models of halo bias. We
therefore conclude that the suppression of small-scale structure in the matter power spectra in $\gamma$CDM and $\nu$CDM takes place independently of the linear background in both overdense and underdense regions. Thus, the clustering properties do not change on the mass scales probed here ($M \gtrsim 10^9 h^{-1} M_\odot$).

5 RESULTS: HALO PROPERTIES

As seen in Section 4, DM–radiation interactions lead to a reduced abundance of low-mass DM haloes. In this section, we focus on three key properties of these haloes: their shape, density profile and spin.

For this analysis, it is important to only consider DM haloes that are dynamically relaxed. We apply the selection criteria presented in Maccio’ et al. (2007) and Neto et al. (2007). The DM haloes must satisfy the following conditions.\footnote{We omit the substructure mass fraction criterion as this is strongly correlated with the centre-of-mass displacement criterion listed (Neto et al. 2007).}

(i) Centre-of-mass displacement: the offset, $s$, between the halo centre of mass, $r_c$, and the potential centre, $r_p$, normalized by the virial radius, $r_{vir}$, satisfies

\[ s = \|r_p - r_{cp}\| < 0.07. \] (15)

(ii) Virial ratio: the total kinetic energy of the halo particles within $r_{vir}$ in the halo rest frame, $T$, and their gravitational potential energy, $U$, satisfies

\[ 2T/\|U\| < 1.35. \] (16)

These criteria reduce the number of haloes in our sample by a factor of 2, but also significantly decrease the scatter as major mergers and their unrelaxed descendants are removed.

In addition to applying these conditions, our mass-averaged results are restricted to: (i) the subset of haloes with a virial mass smaller than $10^{11} h^{-1} M_\odot$, i.e. the mass range that shows a suppression in the halo abundance, and (ii) in order to avoid resolution problems, larger than 1000 particles, i.e. mass bins larger than $\sim 10^{13} h^{-1} M_\odot$. The latter criterion ensures that the estimates for our observables have converged (Power et al. 2003). This lower limit also minimizes the possibility of contamination by spurious structures as they form and mainly affect haloes on small mass scales ($M \lesssim 10^9 h^{-1} M_\odot$); this can be checked by studying their contribution to the HMF plotted in Fig. 5.

5.1 Halo shape

To characterize the shape of DM haloes, we study the following quantities derived from the three eigenvalues ($a \geq b \geq c$) of the inertia tensor, as calculated by the AMIGA halo finder:

(i) sphericity: $c/a$

(ii) elongation: $b/a$

(iii) triaxiality: $(a^2 - b^2)/(a^2 - c^2)$.

In Fig. 7, we plot the sphericity measured from the sample set of relaxed haloes. We observe no significant deviation from CDM for WDM, $\gamma$CDM or $\nu$CDM. The same is true for the elongation and triaxiality, and for different redshifts and interaction cross-sections. Thus, we cannot distinguish these models by the shape of their DM haloes.

5.2 Density profile and concentration

To analyse the density profiles of DM haloes, we first average the density in shells around the centre of mass for all haloes in a given mass bin. A comparison of the results with a fitted NFW profile (Navarro, Frenk & White 1997) reveals a sufficiently good agreement to justify parameterizing the halo profiles in this way.\footnote{The fit starts at a minimum radius from the halo centre as defined by Power et al. (2003) to ensure convergence of the density profile.}

The NFW profile is completely characterized by the concentration parameter, $c_{NFW}$, which is determined by the halo finder using the approximation presented in Prada et al. (2012).

In Fig. 8, we plot the concentration versus mass, cross-section and redshift relations. We observe a significantly lower median lower value of $c_{NFW}$ in the mass bins below the half-mode mass for $\gamma$CDM and $\nu$CDM compared to CDM. This reduction in concentration with increasing interaction cross-section is similar to the effect seen in WDM simulations with reducing particle mass, which has been explained as being due to the delayed formation time of low-mass haloes (Lovell et al. 2012). At these late times, the interacting DM models become (effectively) non-collisional for the cross-sections studied here, in the same way that free-streaming in WDM models becomes negligible at low redshifts. Therefore, it is valid to assume that this lower concentration also originates from the later collapse of the DM haloes in these models.

As we increase the interaction cross-section, the deviation from CDM becomes larger due to an increase in the mass scale of the suppression. Since we have fixed the mass interval, the median concentration decreases as a larger number of high-mass haloes become affected.

Figure 7. Sphericity of relaxed DM haloes for CDM, $\gamma$CDM, $\nu$CDM and WDM at redshift $z = 0$. The symbols show the sphericity in mass bins ranging from $4 \times 10^9$ to $10^{11} h^{-1} M_\odot$ for the different models as labelled. The shaded areas indicate the 95 per cent CL on the median, given the underlying scatter in the halo sample set (small dots), while the error bars mark the 20–80 per cent interval for this distribution. The sphericity of DM haloes measured in WDM, $\gamma$CDM and $\nu$CDM shows no significant deviation from CDM.
5.3 Halo spin

We quantify the spin of DM haloes using the ‘classical’ definition of Peebles (1969),

$$\lambda = \frac{J |E|^{1/2}}{GM_{\text{vir}}^{5/2}},$$

(17)

where $J$ and $E$ are, respectively, the total angular momentum and binding energy of the material within the virial mass, $M_{\text{vir}}$, of a halo.

In the linear and quasi-linear regime, halo spin is described reasonably well using tidal torque theory (hereafter TTT; White 1984) and originates from tidal interactions between collapsing haloes. In this framework, the angular momentum of a (proto)galaxy depends on the mass, but also weakly on the formation time. However, it should be noted that comparisons with numerical simulations have revealed that TTT becomes less applicable as haloes approach turnaround and virialization (Porciani, Dekel & Hoffman 2002). It is still an open question whether haloes acquire significant angular momentum due to mergers with other haloes, as well as from tidal torques (Maller, Dekel & Somerville 2002; D’Onghia & Navarro 2007).

In Fig. 9, we plot the median halo spin against virial mass for the different models. We find a similar reduction and evolution of halo spin for $\gamma$CDM, $\nu$CDM and WDM, compared to CDM.

There are various explanations for the difference in halo spin with respect to CDM. As this effect is seen for haloes consisting of more than a few thousand particles, we can rule out a numerical convergence problem. If it originates solely from tidal torques, then the weak dependence of angular momentum on formation time would yield a smaller spin for the earlier formation time found. If mergers are responsible for spinning up haloes, then the lack of smaller progenitors of low-mass haloes and consequently, smoother accretion on to these haloes in $\gamma$CDM, $\nu$CDM and WDM, would also result in a lower net spin. The fact that the difference remains constant over time while the absolute value grows, seems to support the idea that not only the initial tidal torque on the collapsing structure, but also the environment at late times, influences the spin.

6 CONCLUSION

We have shown that even relatively weak DM–radiation interactions can alter SF on small cosmic scales. In Boehm et al. (2014), we showed that the number of Milky Way satellites is reduced when DM has primordial interactions with photons ($\gamma$CDM) or neutrinos ($\nu$CDM) and that the resulting number of satellites can be used to place constraints on the interaction cross-section. In this paper, we have extended our previous analysis to study the abundance of DM haloes and their internal properties, namely their shape, density profile and spin. We have also compared different models ($\gamma$CDM, $\nu$CDM and WDM) in which the power spectrum of density fluctuations is suppressed on small scales.

The HMFs measured in our simulations show that the $\gamma$CDM and $\nu$CDM models contain more haloes than WDM around a mass of $10^9 h^{-1} M_{\odot}$ for the parameters considered here. This behaviour is not reproduced by various semi-analytical descriptions of the HMF. We note that these mass scales are an order of magnitude larger than the scale on which spurious haloes are expected to make a significant contribution (Wang & White 2007). The source of this overabundance of haloes with respect to WDM needs to be addressed but could be due to the choice of models for the initial conditions in WDM.
Both the NFW concentration parameter in the density profile and the spin show departures from CDM for low-mass haloes. The halo shape, on the other hand, is independent of the DM model. The lower halo concentration and angular momentum may be due to the delayed formation time of low-mass haloes in $\gamma$CDM and $\nu$CDM and are similar to the trends seen in WDM. However, it should be noted that these halo properties do not provide a means to distinguish between $\gamma$CDM, $\nu$CDM and WDM.

Ideally, the next step in this study would be to include baryonic physics in our simulations, which may have an impact on some of the results reported in our DM-only simulations. Bryan et al. (2013) have shown that efficient gas cooling results in an increased halo spin, while AGN feedback counters this trend. The mass–concentration relation of the haloes is very similar when baryons are included (Schaller et al. 2014) and the baryons only affect the radial density profile of the inner core within 5 per cent of the virial radius, producing a contraction. Recent studies also include a possible coupling of DM with dark radiation (Buckley et al., 2014), which leads to a similar suppression of initial fluctuations as seen in our models and, depending on the cross-section, should give rise to similar results as those discussed in this paper.

ACKNOWLEDGEMENTS

JAS is supported by a Durham University Alumnus Scholarship and RJW is supported by the STFC Quota grant ST/K501979/1. This work was supported by the STFC (grant numbers ST/F001166/1, ST/G000905/1 and ST/L00075X/1) and the European Union FP7 ITN INVISIBLES (Marie Curie Actions, PITN-GA-2011-289442). This work was additionally supported by the European Research Council under ERC Grant ‘NuMass’ (FP7-IDEAS-ERC ERC-CG 617143). It made use of the DiRAC Data Centric system at Durham University, operated by the ICC on behalf of the STFC DiRAC HPC Facility (www.dirac.ac.uk). This equipment was funded by BIS National E-infrastructure capital grant ST/K00042X/1, STFC capital grant ST/H008519/1, STFC DiRAC Operations grant ST/K003267/1 and Durham University. DiRAC is part of the National E-Infrastructure. SP also thanks the Spanish MINECO (Centro de excelencia Severo Ochoa Program) under grant SEV-2012-0249.

Figure 9. The spin–mass relation (top) shows a mass-dependence for $\gamma$CDM, $\nu$CDM and WDM, which develops at scales below $\sim 10^{11} \, h^{-1} \, M_{\odot}$. These models are indistinguishable from CDM for more massive haloes. This spin reduction on small scales depends on the interaction cross-section (middle) while the relative deviation from collisionless CDM remains constant over time (bottom). The data points are the median values for the mass bins ranging from $4 \times 10^9$ to $10^{11} \, h^{-1} \, M_{\odot}$, while the shaded regions mark the 95 per cent CL on the median, given the underlying scatter in the halo sample set (small dots in the top plot). The error bars mark the 20–80 per cent interval for this distribution.
