ABSTRACT: The Unitary Group Adapted State Universal Multireference Coupled Cluster (UGA-SUMRCC) theory, recently developed by us (J. Chem. Phys. 2012, 137, 074104), contains exactly the right number of linearly independent cluster operators. This avoids any redundancy of the excitation manifold in a way exactly paralleling the traditional spin−orbital based SUMRCC. The choice of the linearly independent cluster operators inducing the same change of orbital occupancy becomes increasingly cumbersome if we go over to the cases of active CSFs with more than two active quasiparticles. In the present development, we explore several aspects of the UGA-SUMRCC theory: (a) The first is a variant where we have deliberately incorporated redundancy of the cluster amplitudes to simplify the working equations and have shown that it can serve as a very good approximation to the parent UGA-SUMRCC theory for states with more than two valence occupancies. This in turn suggests that it could be a useful avenue to pursue for arbitrary mh−np situation since the working equations assume simpler algebraic structure in such cases. (b) The analyses of the aspects of size extensivity are known to involve greater complexity if they involve various reduced density matrices (RDMs), since the RDMs are not size-extensive quantities. We have presented the proof for UGA-SUMRCC starting from equations containing h−p RDMs via a decomposition involving products of size-extensive cumulants and argue that it has relevance for general cases beyond the h−p model spaces. (c) A useful extension of UGA-SUMRCC lies in formulating the theory for direct calculations of energy differences of spectroscopic interest such as excitation energies, ionization potentials, and electron affinities relative to a closed shell ground state, thus providing attractive alternatives to other allied methods such as SAC-CI, CC-LRT, EOM-CC, STEOM-CC, or ADC. This extension, called UGA-based Quasi-Fock MRCC by us, also leads to exact cancellation of common correlation terms between the initial and final states. Taking a cue from the hierarchical development in Fock-space theories but keeping in mind the advantages of a state-universal (equivalently called a valence specific) theory, our formulation proposes a spin-adapted, accurate, and compact scheme for studying such energy differences. Our results demonstrate superior performance of the method as compared to EOM-CC.

1. INTRODUCTION

Coupled cluster theory1−5 has emerged as by far the most reliable method for energy and properties of molecular electronic states dominated by a single reference function. For states involving quasi-degeneracy, the behavior of the so-called "gold standard" single reference coupled cluster (SRCC), viz. the CCSD(T), becomes erratic, although more involved approaches have been suggested within the framework of SRCC but invoking higher level approximations.2,6 Multi-reference Coupled Cluster (MRCC) theories seem like a more natural choice to handle such situations, and the past three decades have seen considerable developments along several avenues. Despite the undeniable success of several methodologies, the black box use of MRCC theories is still difficult. One major challenge for treating open shell and multireference states (whether at the single or at the multireference level) is the spin adaptation of the coupled cluster wave function. For single determinant nonsinglet states, one usually adopts a spin−orbital based theory to achieve a natural termination at the quartic level and it is well-known that this leads to spin-broken solutions.9 At the MRCC level, the degree of difficulty of spin adaptation depends on the class of MRCC theory one wants to adapt to the proper spin. It is also well documented that spin adaptation has a small but significant role in the accuracy of state energies and that it plays a vital role in the computed properties of molecules. Among the three major approaches to MRCC, viz., valence universal or Fock-Space (VUMRCC or FS-MRCC),10−13 state universal (SUMRCC),14,15 and state specific (SSMRCC),16 only the VUMRCC is inherently spin
adapted. It is also a natural theory for direct computation of energy differences. On the other hand, the Jezierski–Mukherjee–
Maitra (JM) Ansatz used in the last two types of MRCC theories is not inherently spin adapted and in a truncated coupled-cluster
scheme results in spin broken solutions for non-singlet states. The spin adaptation of the JM Ansatz has been the subject of
much research. The most recent endeavor in this direction has been the use of the normal ordered JM-like Ansatz with cluster
operators defined in terms of unitary generators, first introduced by Maitra et al. This Ansatz was first applied by
Maitra et al. in the context of SS-MRCC. The model functions in
this approach are Unitary Group Adapted (UGA) Gel’fand states, and to indicate this the method was termed a
Unitary Group Adapted SSMRCC (UGA-SSMRCC) theory. It
combines the twin advantages of the avoidance of spin con-
tamination and a natural termination of the so-called “direct”
term at the quartic power of the working equations of the
SSMRCC theory. Following an early lead by Mukherjee and
Zaitsevskii, we were led to the same Ansatz to formulate an
UGA-SUMRCC theory which also shares the desirable
properties of the absence of spin contamination as well as
termination of the direct term at the quartic power. We should
mention here that another spin-free generalization of the JM
Ansatz, using unitary generators, was suggested by Datta and
Mukherjee, which is known as COS-SUMRCC. They are structurally closer to the parent spin–
orbital based JM Ansatz and are thus probably the closest spin-
free analogue of JM based MRCC theories. The acronym “COS” signifies a “combinatoric open-shell” situation where the
combinatoric factor accompanying the nth power of the cluster
operator is taken to be the inverse of the “automorphic factor.”
The applications thereof are still confined to one valence
problem, although generalization to encompass multivalence
situations is expected to indicate the potentiality of the approach.
As things are at present, the UGA-based SU- and SS-MRCC theory which also shares the desirable properties of the absence of spin contamination as well as termination of the direct
when to use the simple unitary generators, and in case their
number exceeds the number of linearly independent excitations
one includes redundant operators and provides extra working
functions by invoking sufficiency conditions. Approach b is
totally conceivable and natural for UGA-SSMRCC, since one
is obliged to invoke sufficiency conditions anyway. Such a strategy was indeed adopted by Maitra et al. in their UGA-SSMRCC
and a related theory where the inactive double excitations were treated in an internally contracted manner (UGA-ICID-SSMRCC). In
the realm of UGA-SSMRCC, such sufficiency conditions do not
appear, but it is not mandatory to disallow redundancy such as has
been employed in the UGA-SSMRCC. The use of redundant
cluster operators may lead to simpler working equations whose
efficacy needs to be looked into. In our first formulation, we have
applied the theory for state energies per se of the cationic,
anionic, and excited states. With our choice of vacuum as the
Hartree–Fock function, it is worth looking into the possibility
of a formulation for excitation energy directly in a spin-free
manner. In this paper, we will explore the efficacy and utility of
three distinct modifications:

(i) The first issue, that we will consider, pertains to analyzing
our choice of cluster operators vis-a-vis those used by Li and
Paldus to formulate SUMRCC in a UGA framework. In partic-
ular, we will show that suitable linearly independent cluster
operators can be discerned from simple perturbative reasoning,
although they will no longer lead to orthogonal excited func-
tions. In effect, for the singles–doubles truncation scheme our
choice of combinations appears to be the same as that obtained
from explicit SU2 adaptation. We shall demonstrate that, if
we include some redundant cluster operators, it is possible to
generate a set of spin-free UGA-SUMRCC equations for excited
state energies and excitation energies which are of the same struc-
ture irrespective of spin multiplicity. One avenue which we shall
look into is the possibility of deliberately using certain redundant
cluster operators and concomitantly using suitable sufficiency con-
tions to generate the working equations.

(ii) We shall also try to assess the relative importance of the
inclusion of higher body connected composites in the modified
UGA-SUMRCC equation. Since we have already looked into the
effect of such higher body blocks in the parent UGA-SUMRCC
theory, we think that it is worthwhile to look at the importance of
the higher body contribution in the modified theory also.

(iii) The third issue we will look into is to transcribe the
UGA-SUMRCC theory for state energies to a theory for com-
puting energy differences directly with respect to the ground
state. The Fock space MRCC (FS-MRCC) theory, also known as the
Valence Universal Multi-Reference Coupled Cluster Theory
(VUMRCC), achieves this by carrying out computations on all
subduced valence sectors leading up to the target valence
sector. Our efforts are directed toward the formulation of a
theory for calculating the direct energy difference for the target
sector with respect to the ground state without going through
intermediate valence sectors. Thus, in our strategy, the com-
putation of excitation energy does not involve a prior com-
putation of ionization energy and electron affinity and the
associated cluster amplitudes. We call this formulation a unitary
group adapted Quasi-Fock multireference coupled cluster (UGA-
QFMRCC) theory.

In this paper, we will also discuss in detail several aspects of
connectivity and size extensivity of the parent UGA-SUMRCC
and the consequent size intensity of the excitation energies from UGA-QFMRCC. A general guideline for proving the connectedness of such UGA-MRCC theories is presented, which can be extended to any valence sector and rank of operator, although the consequent derivations become increasingly more involved with the increase in either valence or operator rank.

A study of the performance of all our proposed variants across a chosen set of small molecules is undertaken. We have assessed the trends in energies computed using UGA-SUMRCC and its approximants along a series of basis sets of increasing quality. Statistical data in a reasonable sample space is provided for a more objective analysis.

This paper is organized as follows: In section 2, section 2.1 presents a summary of the development of the UGA-SUMRCC theory, while section 2.2 describes the Ansatz for direct calculation of energy differences and the derivation of the working equations therein. In section 3, the choice of cluster operators in a spin-free UGA-SUMRCC or UGA-QFMRCC is discussed. Section 3.1 demonstrates the rigorous choices we could make and 3.2 deals with certain approximations in the form of sufficiency conditions which could be invoked to simplify the equations. Section 3.3 contains a discussion about the physical content of UGA-QFMRCC, in comparison to other existing methodologies for direct computation of excitation energies. In section 4, a general proof of size extensivity for the parent UGA-SUMRCC and UGA-QFMRCC is delineated. In section 5.1, we discuss the aspects of computational organization and in section 5.2 the computational cost of UGA-QFMRCC. In section 5.3, we present our results and explore the performance of the variant using sufficiency against the parent UGA-SUMRCC and the Quasi-Fock theory against the parent UGA-SUMRCC theory. We also compare our results with those from related theories like EOMCC, 26–29 STEOMCC, 30–32 etc. FCI benchmarks and experimental results are also supplied where available. Section 6 outlines our conclusions and our outlook for the future.

2. THEORETICAL DEVELOPMENTS: THE PARENT UGA-SUMRCC AND ITS QUASI-FOCK (QF) ANALOGUE

We present here a brief summary of the parent UGA-SUMRCC 23 where the aspects of spin-adaptation and termination of the equations become evident. Thereafter, a spin-free valence-specific formulation for direct energy differences which we call UGA-QFMRCC is presented.

2.1. Summary of the UGA-SUMRCC. The objective for formulating the parent UGA-SUMRCC theory 23 was to develop a spin-free theory capable of handling open shell ionized and excited states of a closed shell ground state without spin contamination, while maintaining natural truncation of the direct term and the ease of implementation. This is achieved by taking the following Ansatz for $\Omega$:

$$\Omega = \sum_{\mu} \Omega_{\mu}\{\phi_{\mu}\}$$

(1)

with

$$\Omega_{\mu} = \{\exp(T_{\mu})\}$$

(2)

where the curly bracket above indicates normal ordering with respect to a suitable closed shell vacuum $|0\rangle$. The state $|0\rangle$ is taken in UGA-SUMRCC theory to be the closed shell “core” determinant containing doubly occupied inactive orbitals. The occupancy in $|0\rangle$ is common to all $\phi_{\mu}$’s. The $T_{\mu}$’s are defined as spin-free unitary generators expressed in terms of spatial orbitals. The $\phi_{\mu}$’s are unitary group adapted states, which are Gel’fand Configuration State Functions (CSF) 35 of a specific type. They are generated from the vacuum state $|0\rangle$ by unitary group adapted Gel’fand creators. Another qualifier required for $\phi_{\mu}$ is a string of indices collectively denoted as $n_{\mu}$ which denotes the occupations of the orbitals defining $\phi_{\mu}$. The excited states in our formulation are generated by the action of spin-free unitary generators $\{\{\phi_{\mu}\}\}^{1}$, acting on $\phi_{\mu}$:

$$\{\{\phi_{\mu}\}\} = \{\{\phi_{\mu}\}\}$$

(3)

where $\{\{\phi_{\mu}\}\}$ are in normal order with respect to $|0\rangle$. The functions $\{\{\phi_{\mu}\}\}$ are CSFs but they are neither Gel’fand states nor the SU2 adapted CSFs of Li and Paldus. 37 $\{\{\phi_{\mu}\}\}$’s are linearly independent specific combinations of spatial orbital replacement operators, $\{E_{\mu}\}$, which are generators of the unitary group. The final working equations involve matrix elements between $\phi_{\mu}$’s wherein reduced density matrices (RDM) appear which incorporate the spin information of the target state, and hence how we choose the excited CSFs does not play an important role.

As we have mentioned in section 1, our focus is on electron attached/detached and excited states of closed shell ground states, which can be considered as one-particle (1p)/one-hole (1h) and one-hole—one-particle (1h–1p) sectors with respect to the closed shell state considered as a vacuum, respectively. 1h and 1p model spaces are by construction complete. The 1h–1p model spaces are said to be “quasi-complete,” 35 which is a special case of incomplete model spaces (IMS). It was shown by Mukherjee quite some years ago 36–38 that, to maintain size extensivity for IMS, it is necessary to abandon Intermediate Normalization (IN) of $\Omega$. Interestingly, it was also demonstrated in the context of VUMRCC 34 that for the special case of 1h–1p model spaces, both considering and not considering intermediate normalization leads to the same Bloch equation for those cluster operators which contribute to $H_{\Omega \Omega}$. As it turns out, for the UGA-SUMRCC, such is not the case 40 although the necessary modification in the Bloch equation abandoning IN is fairly straightforward. Thus, the same set of modules as needed to construct the working equations for cluster amplitudes as well as $H_{\Omega \Omega}$ can more or less be used for the generalization of the formalism for CMS. Thus, operationally speaking, we may organize the solution of our working equation in a way quite analogous to that for a CMS.

To generate the working equations for 1h–1p IMS, we start out from the Bloch equation:

$$H_{\Omega \Omega} = \omega_{\Omega \Omega}$$

(4)

where $H_{\Omega \Omega}$ is defined recursively from the model space projection of eq 4.

$$PH_{\Omega \Omega} = P\omega_{\Omega \Omega}P$$

(5)

For the quasi-complete 1h–1p IMS, all the excitation operators $T_{\mu}$ appearing in $\omega_{\Omega \Omega}$ have the interesting property that $T_{\mu}$ can never lead to a transition to any model function $\phi_{\mu}$ by its action on $\phi'_{\mu}$: $\langle \phi'_{\mu}\mid T_{\mu}\mid \phi_{\mu}\rangle = 0$. This property is exploited to effect the minor modifications necessary in the UGA-SUMRCC for the h–p IMS, even if IN for $\Omega_{\mu}$ is not valid. Substituting the Ansatz for $\Omega_{\mu}$ in eq 4, we obtain

$$\langle \exp(T_{\mu})\phi_{\mu}\rangle = \sum_{T_{\mu}}\langle \exp(T_{\mu})\mid \exp(T_{\mu})W_{\mu}\rangle\phi_{\mu}$$

(6)

$$\langle \exp(T_{\mu})\phi_{\mu}\rangle = \sum_{T_{\mu}}\exp(-T_{\mu}\exp(T_{\mu})W_{\mu}\rangle\phi_{\mu}$$

(7)
where

\[ \overline{H}_\mu = \int \exp(T_\mu) \]

is a compact notation of the series:

\[ \overline{H}_\mu = \{ H \} + \{ H T_\mu \} + \frac{1}{2} \{ H T_\mu T_\mu \} + ... \]

(9)

The “contraction,” \( A \), connecting two strings of operators \( A \) and \( B \) denotes the sum of all possible contractions involving all pairs of operators from both \( A \) and \( B \). Terms like \( \{ H T_\mu T_\mu \} \) etc. involve contractions between \( H \) and the various \( T_\mu \)'s, excluding contractions between the operators of different \( T_\mu \)'s.

The operator, \( W_{\nu\mu} \), is a closed operator labeled by orbitals distinguishing \( \phi_\mu \) and \( \phi_\nu \). It transforms \( \phi_\mu \) to \( \phi_\nu \) via the relation

\[ W_{\nu\mu} |\phi_\mu\rangle = |\phi_\nu\rangle \langle H_{\text{eff}} |\phi_\mu\rangle \]

(10)

It is composed of operators of various ranks, the lowest rank being the number of orbitals by which \( \mu \) and \( \nu \) differ. \( W_{\nu\mu} \) may also contain components with any number of spectator scatterings involving creation and destruction of common active orbitals of \( \phi_\mu \) and \( \phi_\nu \), resulting in the ranks of the operator being higher. The spectators need not all be diagonal, it is only essential for the labels of the spectators to be one of the common orbitals of \( \mu \) and \( \nu \).

Equation 7 is satisfied if we invoke the following equality:

\[ \langle |\phi_\mu\rangle \rangle = \sum [\exp(-T_\mu \exp(T_\nu \exp(T_\mu_{\text{eff}} \exp(T_\nu_{\text{eff}}) \exp(T_\mu_{\text{eff}})))) |\phi_\mu\rangle = 0 \]

(11)

Now, we will define two components from this equation:

\[ G_{\mu,\nu} = \langle |\phi_\mu\rangle \rangle - \sum [\exp(-T_\mu \exp(T_\nu \exp(T_\mu_{\text{eff}} \exp(T_\nu_{\text{eff}}) \exp(T_\mu_{\text{eff}}))) |\phi_\nu\rangle \]

\[ G_{\nu,\mu} = \langle |\phi_\mu\rangle \rangle - \sum [\exp(-T_\mu \exp(T_\nu \exp(T_\mu_{\text{eff}} \exp(T_\nu_{\text{eff}}) \exp(T_\mu_{\text{eff}}))) |\phi_\nu\rangle \]

(12)

Here, “ex” refers to the excited and “cl” to the closed component of the operator: an operator, \( A_{\mu,\nu}^{\text{ex}} \), excites to virtual functions by its action on \( \phi_\mu \); an operator, \( A_{\mu,\nu}^{\text{cl}} \), converts \( \phi_\mu \) to a sum of model space functions:

\[ A_{\mu,\nu}^{\text{cl}} |\phi_\mu\rangle = \sum |\phi_\nu\rangle \langle \phi_\nu | A_{\mu,\nu}^{\text{cl}} |\phi_\mu\rangle \]

(14)

Projection of \( |\phi_\mu\rangle \) on \( G_{\mu,\nu} |\phi_\mu\rangle \) gives

\[ \langle \phi_\mu | [\overline{H}_\mu]_{\text{cl}} |\phi_\mu\rangle = \langle \phi_\nu | \sum [\exp(-T_\mu \exp(T_\nu \exp(T_\mu_{\text{eff}} \exp(T_\nu_{\text{eff}}) \exp(T_\mu_{\text{eff}}))) |\phi_\mu\rangle = R_{\mu,\nu} - 0 \]

(15)

Projecting with \( |\phi_\nu\rangle \) on \( G_{\mu,\nu} |\phi_\mu\rangle \) leads to

\[ \langle \phi_\mu | [\overline{H}_\mu]_{\text{cl}} |\phi_\nu\rangle = \langle \phi_\nu | \sum [\exp(-T_\mu \exp(T_\nu \exp(T_\mu_{\text{eff}} \exp(T_\nu_{\text{eff}}) \exp(T_\mu_{\text{eff}}))) |\phi_\nu\rangle = R_{\nu,\mu} - 0 \]

(16)

Equation 16 is to be used for determining the cluster amplitudes of \( T_\mu \). We note that the first term, called the “direct term,” will necessarily truncate at quartic power in all situations.

The second, so-called, “coupling term” will also naturally terminate, but the maximum power will be controlled by the rank of the valence sectors under consideration.

We may mention here that the lack of IN for \( \Omega \) requires an iterative solution for \( H_{\text{eff}} \) via eq 5. In our actual implementation, we have combined this iteration with that used for obtaining the cluster amplitudes of \( T_\mu \). We will elaborate on this in section 5.1.

### 2.2. Formulation of the Quasi-Fock UGA-SUMRCC.

The inspiration for the UGA-QFMRCC theory comes from the development of the parent UGA-SUMRCC and the earlier Quasi-Fock theory of Mukhopadhyay and Mukherjee. In the parent UGA-SUMRCC theory, the t-amplitudes required were only those for the target valence sector (say, excited state). Here, our aim is not to obtain the state energy itself but the energy difference with respect to a subduced valence sector (say, ground state). The benefit of a correlated theory for obtaining energy differences lies in the exact analytic cancelation of the common correlation energy of the two states, leading to a treatment of the common correlation terms of both states on equal footing even under truncated schemes. The theory for computing energy differences with respect to the ground state requires an appropriate parametrization of the wave operator where cluster operators inducing correlation of the ground state should also appear explicitly. We use the notation \( (\nu,\mu) \) to denote an \( m \)-th valence sector and \( T^{(\nu,\mu)} \) to denote the cluster operators thereof.

The theory we will use in this respect first computes the amplitudes for the \((0,0)\) valence sector which generates the cluster operators of the ground state and then—quite unlike the approach of the Fock space theory—directly computes the amplitudes for the target \((\nu,\mu)\) sector. In the FS-MRCC theory, in contrast we would have had to build the target \( \Omega \) hierarchically, starting from the \((0,0)\) sector of the Fock space, which is spanned by the HF function, taken as the vacuum. The operators \( \Omega^{(1,0)} \) and \( \Omega^{(0,1)} \) respectively are constructed in the next stage of solution and provide information on the \((1,0)\) and \((0,1)\) sectors of the Fock space. Next comes the operators \( \Omega^{(2,1)} \) of the target sector, viz. the \( \nu \)-th model space. Our theory bypasses the \((1,0)\) and \((0,1)\) sectors, and this is the reason why such a theory has been called a Quasi Fock MRCC (QF-MRCC) in the literature.

Our intention is to develop a spin-free UGA version of a QF-MRCC, using the same strategy as has been formulated in our UGA-SUMRCC, for the direct computation of such energy differences as ionization potential (IP), electron affinity (EA), and excitation energy (EE). The performance of such a formulation also provides us some insights regarding the physics incorporated in our excited state calculations using UGA-SUMRCC as against that in the description of the ground state using SRCC.

We should mention here that there exist several closely related theories, viz. Valence Universal MRCC (VUMRCC), the so-called double-curly VUMRCC which uses a special combinatoric cluster Ansatz, and Similarity Transformed Equation of Motion Coupled Cluster (STEOMC). VUMRCC and the double curly VUMRCC utilize a valence universal \( \Omega \), while all the other methods involve the calculation of ground state amplitudes which are used to transform the Hamiltonian before the computation of the energy differences. UGA-QFMRCC falls in the second category. However, the Ansatz for UGA-QFMRCC is richer in structure, and we expect a better performance. We have also employed different approximate schemes analogous to those in the UGA-SUMRCC for UGA-QFMRCC to see their performance for this method.

In the present formulation, our first assumption is that the ground state is well described by a single reference theory, namely single-reference coupled cluster theory. Therefore, \( \exp(T) \) parametrization of the wave operator, acting on the HF function for the ground state is sufficient. We will treat excited states as multireference in a state universal framework, and for the analogous treatment of the common correlation part, the cluster amplitudes will include the exact ground state \( T \)'s for every model function and the differential correlation will be
treated by the $S_\nu$ amplitudes. This idea naturally suggests that our choice of Ansatz for UGA-QFMRCC should be of the form
\begin{equation}
\Omega_\nu = \exp(T)\{\exp(S_\nu)\}
\end{equation}

We distinguish carefully between the operators $T_\nu$ used in UGA-SUMRCC and $S_\nu$ introduced here in the context of UGA-QFMRCC. The $T_\nu$'s in UGA-SUMRCC represent the actual correlation of the target state contributed by the virtual excitations from $\phi_\nu$ as in the parent UGA-SUMRCC theory. The $S_\nu$'s, on the other hand, represent the differential correlation and relaxation of the state, i.e., the difference in the correlation contribution of $T_\nu$ of the target state and the subduced state with respect to which the energy difference is required.

We explain below the theory for excitation energy, but the same considerations apply also to any other energy difference of interest. The ground state $T$-amplitudes are first calculated for the closed shell reference state and so, the first part of our Ansatz is known. The working equations to be derived are, thus, for $S_\nu$'s of the excited state only. As we have emphasized above, the hierarchical generation of the $S_\nu$'s going through the various lower valence sectors as in Valence Universal Multireference Coupled Cluster (VUMRCC)\textsuperscript{10-13} is entirely bypassed.

Having solved for $T$, a dressed Hamiltonian is defined as
\begin{equation}
\hat{H} = \exp(-T) \hat{H} \exp(T)
\end{equation}

and $H_{\text{eff}}$ are now partitioned to separate out the ground state energy.
\begin{equation}
\hat{H} = E_{\nu} + \hat{H}
\end{equation}
\begin{equation}
H_{\text{eff}} = E_{\nu} + \hat{H}_{\text{eff}}
\end{equation}
\begin{equation}
\hat{H}_{\text{eff}} = \{\phi_\nu | \tilde{W}_{\nu\mu} | \phi_\mu\}
\end{equation}

$\tilde{W}_{\nu\mu}$ may be considered as the closed operator whose matrix element with respect to $\{\phi_\nu\}$ and $\{\phi_\mu\}$ corresponds to $\hat{H}_{\text{eff}}$. Invoking the Bloch equation for the model function $\phi_\mu$
\begin{equation}
H_{\text{eff}} \phi_\mu = \sum_{\nu} \Omega_{\nu \mu} |\phi_\nu\rangle
\end{equation}
\begin{equation}
H \exp(T) \{\exp(S_\nu)\} |\phi_\nu\rangle = \sum_{\nu} \exp(T) \{\exp(S_\nu)\} |\phi_\nu\rangle \hat{H}_{\text{eff}}
\end{equation}

and operating with $\exp(-T)$ from the left, we have
\begin{equation}
\exp(-T) H \exp(T) \{\exp(S_\nu)\} |\phi_\nu\rangle
\end{equation}
\begin{equation}
\exp(-T) H \exp(T) \{\exp(S_\nu)\} |\phi_\nu\rangle
\end{equation}

Using the definitions in eqs 19-21, we can cancel $E_{\nu}$ from either side of eq 26 to give
\begin{equation}
\{\exp(S_\nu) \hat{H} \exp(S_\nu)\} |\phi_\nu\rangle = \sum_{\nu} \{\exp(S_\nu) \exp(S_\nu) \tilde{W}_{\nu\mu} \} |\phi_\mu\rangle
\end{equation}
\begin{equation}
\{\exp(S_\nu) \hat{H} \exp(S_\nu)\} |\phi_\nu\rangle = \sum_{\nu} \{\exp(S_\nu) \exp(-S_\nu) \exp(S_\nu) \tilde{W}_{\nu\mu} \} |\phi_\mu\rangle
\end{equation}

$\tilde{W}_{\nu\mu}$ just as the operator $W_{\nu\mu}$ defined in eq 21, is a closed operator which is necessarily labeled by orbitals distinguishing $\phi_\nu$ and $\phi_\mu$. It consists of operators of various ranks, the lowest rank being the number of orbitals by which $\mu$ and $\nu$ differ. Let us call them closed transfer operators without spectators. However, $\tilde{W}_{\nu\mu}$ may contain components with an arbitrary number of spectator scatterings involving creation and destruction of common active orbitals of $\phi_\nu$ and $\phi_\mu$. In such cases, the ranks of the operator may be higher than that for $W_{\nu\mu}$ without spectators, although it scatters from $\mu$ to $\nu$. The spectators need not all be diagonal, it is only essential for the labels of the spectators in $W_{\nu\mu}$ to belong to the set of common orbitals of $\phi_\nu$ and $\phi_\mu$.\footnote{Equation 28 is satisfied if the following equality is invoked:}
\begin{equation}
\langle \tilde{H}(\exp(S)) | \phi_\nu \rangle - \sum_{\nu} \{\exp(S_\nu) \exp(-S_\nu) \exp(S_\nu) \tilde{W}_{\nu\mu} \} |\phi_\mu\rangle = 0
\end{equation}
\begin{equation}
\langle \tilde{H}(\exp(S)) | \phi_\nu \rangle - \sum_{\nu} \{\exp(S_\nu) \exp(-S_\nu) \exp(S_\nu) \tilde{W}_{\nu\mu} \} |\phi_\mu\rangle = 0
\end{equation}

After having solved for the amplitudes of $\{S_\nu\}$, we obtain the sought after energy differences, $\Delta E_{\nu \mu}$ and the associated coe\textsuperscript{c}cients, $\{c_{\nu \mu}\}$, from the eigenvalue equation:
\begin{equation}
\sum_{\nu} \Omega_{\nu \mu} c_{\nu \mu} = \sum_{\nu} \{\exp(S_\nu) \exp(S_\nu) \tilde{W}_{\nu\mu} \} c_{\nu \mu} = \Delta E_{\nu \mu}
\end{equation}

3. CHOICE OF CLUSTER OPERATORS IN THE CCSD TRUNCATION SCHEMES FOR UGA-SUMRCC AND UGA-QFMRCC

3.1. Use of Nonredundant Excitation Manifold. We begin with the comment that, in the SUMRCC method using the JM Ansatz in a spin--orbital basis, the set of excited functions, $\{\phi_\nu\}$, reached by the action of $T_\nu$'s on the various model functions $\phi_\mu$, are complete in the sense that for each of the $N$ active model functions $\phi_\mu$, if $M_\mu$ is the number of virtual functions reached from $\phi_\mu$, then the total number of cluster amplitudes is $M = \Sigma M_\mu$. The corresponding dimension of the Hilbert space spanned by the virtual functions for all the $N$ roots is equal to $M = \Sigma M_\mu$. Since $N_\mu = M_\mu$ and the sum over $k$ is exactly equal to the sum over $\mu$, $M_{\text{act}} = M$ and we have no redundancy in the SUMRCC theory. Moreover, in a spin--orbital formulation, the virtual determinant, $\chi_\nu$, reached from a model determinant, $\phi_\nu$, is uniquely specified by the indices of the occupied and unoccupied spin--orbitals in $\phi_\nu$. In a spin-free UGA-MRCC, one would naturally want to retain the spirit of the spin--orbital based SUMRCC in that one would choose only those operators in $\phi_\nu$ which for a given change of orbital occupancy would lead to just the linearly independent set of $\chi_\nu$'s with the same inactive and active occupancy. Since operators defined in terms of spatial orbitals do not have a one to one correspondence with pairs $\{\phi_\nu', \phi_\mu\}$, a proper choice of linearly independent operators becomes important. However, an overcompleteness can arise within the excitation manifold for one model function, $\phi_\mu$, when more than one excitation operator leads to the same excited function. An excited function is characterized by the occupancies of the orbitals and the spin coupling among the singly occupied orbitals. Given the number of open shells (singly occupied orbitals) and the net spin of the state, the number of linearly independent (LIN) functions is known, and only as many equations are logically available as there are LIN functions. It thus is logical to choose suitable linearly independent combinations of the various excitation operators of $S_\nu$ inducing the same orbital occupancy changes in the set $\{S_\nu\}$. If this proper selection is not done to attain the exact number of LIN operators and instead every unitary generator is used in $T_\nu/S_\nu$ to generate excited CSFs, they would
lead to an overcomplete set of virtual functions. Several UGA-based approaches in the context of SUMRCC have been proposed and implemented, mainly by Li and Paldus.\textsuperscript{17,33} Paldus and Li had earlier formulated a theory in which Gel’fand–Tsetlin (GT) excited states were generated.\textsuperscript{42,43} As the formalisms were rather complex, they had exploited SU2 group adaptation of the generators to form their excitation operators. The generators of Gel’fand states are combined to form the linearly independent operators of an SU2 group. They will not necessarily follow the one-to-one orthogonality relation of the corresponding Gel’fand adapted excited states of an $U(n_{t} + n_{s} + n_{c})$ group where $n_{t}$ denotes the number of inactive core orbitals, $n_{c}$ denotes the number of active (equivalently, valence) orbitals, and $n_{s}$ denotes the number of inactive virtual orbitals. They argued that, to retain size extensivity, the states must obey this orthogonality relationship. They had also normalized the resulting operators.

In the present formalism, we have generated the working equations by projecting the set of Bloch equations to the excited state CSF, $\chi_{\mu}^i$. Our operator combinations are LIN although not necessarily orthogonal. The projections naturally lead to the appearance of $n$-body RDMs in the working equations. The connectedness of the projected equations is sufficient to prove the size-extensivity of our formalism.

We propose to choose our combinations of operators in a practicable manner within the framework of our theory, using a two-pronged approach: a perturbative analysis of our working equations and the knowledge of the number of LIN functions. Whether these operators produce mutually orthogonal virtual functions, $\chi_{\mu}^i \forall i$ is something we do not consider at all. We illustrate our scheme using an example.

We will henceforth denote by labels $i, j, ...$ etc. the inactive holes; by $a, b, ...$ etc. the inactive particles; by $I, J, ...$ etc. the active holes; and by $A, B, ...$ etc. the active particles. Excitations involving an orbital, "$i^\uparrow$" and an orbital, "$a^\uparrow$" can belong to two classes: (i) not involving a change in occupancy of the active hole ($I$) or particle ($A$) orbitals or (ii) involving a change in occupancy of the active hole or particle orbitals. $\chi_{i}^i, \chi_{i}^a$, and $\chi_{a}^i$ belong to the first class. It is enough if we explain our strategy using the $T$s belonging to this class. For those belonging to the second class, like $\chi_{i}^b$, or $\chi_{a}^a$, etc., an exactly analogous analysis can be used.

To discern which of the excitation operators accompanying the amplitudes, $\chi_{i}^i, \chi_{i}^a$, and $\chi_{a}^i$, are linearly independent, we first construct the projection equations for all of them and look at their algebraic structures. The explicit working equations for $\chi_{i}^i, \chi_{i}^a$, and $\chi_{a}^i$ operators in the 1h–1p sector are as follows:

$$G_{i}^i = G_{i}^a + G_{a}^i - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{i}^l = 0$$

$$G_{i}^a = G_{i}^a - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{i}^l = 0$$

$$G_{a}^i = G_{a}^i - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{a}^l = 0$$

$$G_{i}^j = G_{i}^a + G_{a}^i - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{i}^l = 0$$

$$G_{i}^a = G_{i}^a - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{i}^l = 0$$

$$G_{a}^i = G_{a}^i - \frac{1}{2} G_{i}^j - \frac{1}{2} G_{a}^j + 2 G_{a}^l = 0$$

where

$$\chi_{\mu}^i = \langle \phi_{\mu}^i | E_{\mu}^{i} \rangle \phi_{\mu}^i = 1$$

$$\gamma_{\mu}^i = 2 - \langle \phi_{\mu}^i | E_{\mu}^{i} \rangle \phi_{\mu}^i = 2 - \chi_{\mu}^i = 1$$

$$\Gamma_{\mu}^{i} = \langle \phi_{\mu}^i | E_{\mu}^{i} \rangle \phi_{\mu}^i = -1$$

$$\Gamma_{\mu}^{a} = \langle \phi_{\mu}^a | E_{\mu}^{a} \rangle \phi_{\mu}^a = 1 + (-1)^{S}$$

where $S$ is the spin of the CSF, $\phi_{\mu}$ (i.e., $S = 0$ for singlet and $S = 1$ for triplet). To obtain the LIN combinations of operators, it is sufficient to consider up to two-body G-blocks. For the singlet excited states, using the values of the RDMs as in eq 35, we arrive at the following equations:

$$G_{i}^i - G_{i}^a + G_{a}^i + \frac{1}{2} C_{i}^{j} - \frac{1}{2} C_{a}^{j} = 0$$

$$G_{i}^a - G_{i}^a + G_{a}^i + 2 C_{i}^{j} = 0$$

$$G_{a}^i - G_{a}^i + G_{i}^i = 0$$

Similarly, the equations for triplet states are

$$G_{i}^i - G_{i}^a + G_{a}^i + \frac{1}{2} C_{i}^{j} - \frac{1}{2} C_{a}^{j} = 0$$

$$G_{i}^a - G_{i}^a + G_{a}^i + 2 C_{i}^{j} = 0$$

$$G_{a}^i - G_{a}^i + G_{i}^i = 0$$

We note here that eq 38 and eq 39 are identical. Thus, $\chi_{i}^i$ and $\chi_{a}^i$ are linearly dependent operators. After a slight mathematical manipulation, the set of equations can be equivalently written as

$$G_{i}^i - G_{i}^a + G_{a}^i = 0$$

$$G_{i}^a - G_{i}^a + G_{a}^i = 0$$

The first order perturbative estimate of the cluster amplitude $\chi_{i}^i$ from eq 43 is given by

$$1^{T_{i}^{(i)}} \approx \frac{(f_{i}^{a} - V_{i}^{d} + V_{i}^{a}) \{ E \}}{f_{i}^{a} - V_{i}^{d} + V_{i}^{a} = f_{i}^{a} + V_{i}^{d} - V_{i}^{a} = 1^{T_{i}^{(i)}} \{ E \}}$$

Similarly, eq 44 indicates that

$$2^{T_{i}^{(i)}} \approx \frac{(V_{i}^{a} - V_{i}^{a}) \{ E \}}{f_{i}^{a} - V_{i}^{d} + V_{i}^{a} = f_{i}^{a} + V_{i}^{d} - V_{i}^{a} = 2^{T_{i}^{(i)}} \{ E \}}$$

The quantities $f_{i}^{p}$ ($p = i$ or $a$) are orbital energies, and $V_{i}^{m}$ are the two-body matrix elements. Thus, the corresponding operators, $\{ E_{i}^{a} \}$ and $\{ E_{i}^{m} \}$, should be treated on the same footing in a combination as guided by the first order estimate. We should therefore introduce $2^{T_{i}^{(i)}} \equiv 2^{T_{i}^{(i)}} \{ E_{i}^{a} \} - \{ E_{i}^{m} \}$ with a common amplitude $2^{T_{i}^{(i)}}$ as the unknown and use eq 44 for its determination.

Thus the first class of operators contains $1^{T_{i}^{(i)}} \{ E \}$ and $2^{T_{i}^{(i)}} \equiv 2^{T_{i}^{(i)}} \{ E_{i}^{m} \} - \{ E_{i}^{m} \}$. Similarly, the second class of operators
contains $2\mathcal{T}_n = \mathcal{P}[\{\mathcal{E}_{\text{UA}}\} - 0.5\{\mathcal{E}_{\text{OA}}\}]$ and $2\mathcal{T}_n = \mathcal{P}[\{\mathcal{E}_{\text{OA}}\} - 0.5\{\mathcal{E}_{\text{OA}}\}]$.

The triplet equations, on the other hand, do not indicate any linear dependence, and hence, all three amplitudes, $t_e$, $\tilde{t}_e$, and $t_e^{\text{corr}}$ can be used.

A comparative list of Paldus and our operators is provided in Tables 1 and 2, wherein the operators chosen by Li and Paldus are converted to normal order with respect to the HF function for an easy comparison with the model function:

| Table 1. Choices of $T$'s for Singlet 1h-1p States | UGA-SUMRCC | OSCC (Paldus and Li) | Paldus | UGA-SUMRCC | OSCC (Paldus and Li) |
|-----------------------------------------------|-------------|----------------------|--------|-------------|----------------------|
| $\mathcal{T}_1$ | $t_e(\mathcal{E}_1)$ | $t_e(\mathcal{E}_1)$ | $t_e(\mathcal{E}_1)$ | $t_e(\mathcal{E}_1)$ | $t_e(\mathcal{E}_1)$ |
| $\mathcal{T}_2$ | $t_e^2(\mathcal{E}_2)$ | $t_e^2(\mathcal{E}_2)$ | $t_e^2(\mathcal{E}_2)$ | $t_e^2(\mathcal{E}_2)$ | $t_e^2(\mathcal{E}_2)$ |
| $\mathcal{T}_3$ | $t_e^3(\mathcal{E}_3)$ | $t_e^3(\mathcal{E}_3)$ | $t_e^3(\mathcal{E}_3)$ | $t_e^3(\mathcal{E}_3)$ | $t_e^3(\mathcal{E}_3)$ |
| $\mathcal{T}_4$ | $t_e^4(\mathcal{E}_4)$ | $t_e^4(\mathcal{E}_4)$ | $t_e^4(\mathcal{E}_4)$ | $t_e^4(\mathcal{E}_4)$ | $t_e^4(\mathcal{E}_4)$ |
| $\mathcal{T}_5$ | $t_e^5(\mathcal{E}_5)$ | $t_e^5(\mathcal{E}_5)$ | $t_e^5(\mathcal{E}_5)$ | $t_e^5(\mathcal{E}_5)$ | $t_e^5(\mathcal{E}_5)$ |
| $\mathcal{T}_6$ | $t_e^6(\mathcal{E}_6)$ | $t_e^6(\mathcal{E}_6)$ | $t_e^6(\mathcal{E}_6)$ | $t_e^6(\mathcal{E}_6)$ | $t_e^6(\mathcal{E}_6)$ |
| $\mathcal{T}_7$ | $t_e^7(\mathcal{E}_7)$ | $t_e^7(\mathcal{E}_7)$ | $t_e^7(\mathcal{E}_7)$ | $t_e^7(\mathcal{E}_7)$ | $t_e^7(\mathcal{E}_7)$ |
| $\mathcal{T}_8$ | $t_e^8(\mathcal{E}_8)$ | $t_e^8(\mathcal{E}_8)$ | $t_e^8(\mathcal{E}_8)$ | $t_e^8(\mathcal{E}_8)$ | $t_e^8(\mathcal{E}_8)$ |
| $\mathcal{T}_9$ | $t_e^9(\mathcal{E}_9)$ | $t_e^9(\mathcal{E}_9)$ | $t_e^9(\mathcal{E}_9)$ | $t_e^9(\mathcal{E}_9)$ | $t_e^9(\mathcal{E}_9)$ |
| $\mathcal{T}_{10}$ | $t_e^{10}(\mathcal{E}_{10})$ | $t_e^{10}(\mathcal{E}_{10})$ | $t_e^{10}(\mathcal{E}_{10})$ | $t_e^{10}(\mathcal{E}_{10})$ | $t_e^{10}(\mathcal{E}_{10})$ |

The perturbative analysis is workable only up to two-body operators. In the context of a two active electron situation, we know that the excited functions must be either symmetric (triplet) or antisymmetric (singlet) depending on whether the model function is triplet or singlet, respectively. This consideration allows us to construct combinations of operators. Beyond two-body operators for more than two active electrons, taking explicit combination of operators becomes rather cumbersome and difficult in any scheme but doable in principle via the combination of unitary operators adapted to SU2.

3.2. Deliberate Use of Sufficiency Conditions. In the previous subsection, we have seen that suitable combinations of operators need to be chosen to ensure a linearly independent excitation manifold. This would become increasingly complicated as we proceed to higher valence sectors. There is a possibility that inflating the number of equations by invoking sufficiency conditions would allow us to use all possible unitary generators (E) without having to bother about what combination to use. We explore this possibility for a 1h−1p sector using both UGA-SUMRCC and UGA-QMFRCC. The true benefit of this scheme is, however, expected to be in the extension of these theories to higher valence sectors and higher body T operators. In the context of the example mentioned in section 2.1, this would mean using the following set of equations:

$$G^u - G^d_{\text{UA}} + G^d_{\text{LA}} - G^d_{\text{OA}} = G^d_{\text{OA}}$$

Similarly, the equations for the other dependent operators may be separated out. The excitation manifold here is overcomplete with the same function generated more than once. Unlike the space of Gel’fand adapted excited functions, our manifold in the parent UGA-SUMRCC is linearly independent but nonorthogonal. On invoking sufficiency, the operators become linearly independent. A possible hurdle is the independent evaluation of dependent amplitudes which might destroy the relative contribution of these amplitudes. The performance of this approximation with artificial inflation of unknowns and equations has thus to be carefully assessed to test its efficacy. The results are presented in section 3.3.

3.3. Treatment of Orbital Relaxation and Differential Correlation for Excitation Energies (EE) in UGA-QF vs Allied Theories. Whenever multiple valence sectors are involved in the description of a state, it is pertinent to discuss the physics incorporated in a theory for direct determination of excitation energy (EE) under three headings: (1) an appropriate choice of the wave operator for the excited state which ensures exact cancellation.
of the correlated ground state energy in the EE, (2) orbital relaxation of the ground state orbitals, and (3) differential correlation. The two latter points describe the changes attendant on excitation. Since the formulation of our UGA-QFMRCC shares all the three characteristics 1–3 above with the Fock-space MRCC (FS-MRCC),\textsuperscript{10−11} Eigenvalue Independent Partitioning (EIP) in Fock space (FS-EIP),\textsuperscript{56} and the Similarity Transformed Equation of Motion CC (STEOM-CC) theory,\textsuperscript{30−32} it is pertinent to have a comparative perspective of all these theories.

All four theories use the factorized cluster Ansatz for the wave operator of the excited state:

\[ \Omega = \exp(T)\Omega_s \]  \hspace{1cm} (50)

where \( \exp(T) \) is the wave operator for the ground state in the CC form and \( \Omega_s \) introduces the effects of valence correlation, core−valence interaction, and orbital relaxation/differential correlation. It is in the quantitative inclusion of the various physical effects induced by \( \Omega_s \), that the four theories differ. The factorized cluster Ansatz allows the complete cancellation of the ground state correlation energy via the use of the dressed Hamiltonian, \( \tilde{\bar{H}} \) of eq 18, which allows a clean separation of the ground state energy \( E_s \) and the operator part of \( \tilde{\bar{H}} \), as shown in eq 19. Thus, for the same truncation scheme for the ground state, the magnitude of the ground state energy subtracted for all four theories is exactly the same. The effective Hamiltonian, \( \tilde{\bar{H}}_{\text{eff}} \) generating the energy differences depends on \( \Omega_s \), which may be different for the four theories. This is reflected in eq 21 where \( \tilde{\bar{H}}_{\text{eff}} \) depends on \( \Omega_s \), which may be different for the four theories in actual applications. The FS-MRCC, FS-EIP, and STEOM-CC all invoke the concept of valence universality\textsuperscript{10} and express \( \Omega_s \) as

\[ \Omega_s = \{ \exp S \} \]  \hspace{1cm} (51)

where \( S \) consists of cluster operators of different valence sectors: \( S = S^{(01)} + S^{(10)} + S^{(11)} \). It is pertinent to have a comparative perspective of all these theories.

Model spaces where \( A \) is an active virtual orbital (say, for a 1p or 1h−1p model space). In FS-MRCC or FS-EIP/STEOCC, which are responsible for orbital relaxation due to change in valence occupancy, are present up to linear power only while in UGA-QFMRCC, the set of operators \( E_t^s \), \( E_t^d \), \( E_A^s \), and \( E_A^d \), which are clubbed together as \( \epsilon^{(\mu)} \) (denoted with bold vertices in Figure 2, which occurs to all powers.

Hence, physics is incorporated to a greater extent in UGA-QFMRCC on two counts: (a) knowledge of the S amplitudes regarding the valence occupancies \( I \) and \( A \) and (b) a full exponential involving \( S_{\mu}^w \) (with \( \phi_{\mu} \equiv \phi_{\mu}^2 \)). When \( E_t^d \) is LIN with \( E_t^s \), however, it occurs up to linear power even in UGA-QFMRCC. The correlation on the other hand is incorporated by the two-body excitation operators and differential correlation by three-body operators with direct and exchange spectators as in Figure 2. Thus, in FS-MRCC or FS-EIP/STEOCC, a CCSD

Figure 1. FS-MRCC/FS-EIP/STEOCC (a,b) vs UGA-QFMRCC (d,e)−Orbital relaxation diagrams. Note that for the (0,1) sector and the target (1,1) sector, the operators in b from normal-ordered \( \Omega_s \) terminates at linear power while d subsumes a and b and, thus, occurs to all powers. Following the usual convention, inactive lines are denoted by single arrows, and the active lines are denoted by double arrows. The filled circle vertex in parts d and e depict the model space dependence of the inactive excitation operator of \( S_{\mu} \).

Figure 2. FS-MRCC/FS-EIP/STEOCC vs UGA-QFMRCC-Differential correlation. Note that for the (0,1) sector, the operators b and c from normal-ordered \( \Omega_s \) are necessary for introducing differential correlation but are absent in a singles−doubles truncation while d subsumes a and b and, thus, occurs to all powers. The operator, c is absent in UGA-QFMRCC, but some implicit contribution through the G-block shown in e is possible.
truncation scheme has no such differential correlation operators while the UGA-QFMRCC easily incorporates the direct spectator contributions to all orders. The exchange spectator blocks implicitly contribute in the projection equations. Other than spectator scatterings, orbital relaxation and correlation relaxation also occur in the presence of multiple valence occupancies. In order to fully include all such contributions, it would be necessary to use up to \((m + n + 2)\) rank operators for an \((m,n)\)-valence sector such as in Figure 3, which is not a practical possibility in situations where orbital relaxation is very high, such as core electron ionization and excitation. Preliminary investigations indicate that UGA-QFMRCC is considerably better than EOM-CC in these cases, although COS-CC is even better, as expected.

4. SIZE EXTENSIVITY OF THE PARENT UGA-SUMRCC AND EVALUATION OF SIZE INTENSIVE ENERGIES IN UGA-QFMRCC

In this section, we recapitulate the aspects of size extensivity of UGA-SUMRCC and further elaborate on how the connectedness of equations with apparently disconnected terms arising from the occurrence of \(n\)-body RDMs solely on one fragment of a projected composite may be demonstrated to be actually connected. There are two levels of connectivity to be analyzed. First, we must demonstrate that the \(G\) blocks themselves are connected composites. Next, we must be able to show that the different components of the working equations obtained on projection by \(\langle \gamma_i \rangle\) are connected among themselves. Since RDMs are not in general connected quantities, we must conclusively show that all of the terms in the matrix element \(\langle \gamma_i | G^{(2)}(\nu) | \psi_j \rangle\), with the potential of being disconnected, either necessarily have common labels with the \(G\) blocks or cancel on algebraic manipulation. In essence, one needs to show that the terms contributing to each projection equation are connected entities and the cluster amplitudes of the set \(T_{\mu}\) are connected.

4.1. Connectivity of the \(G\) Blocks. To start with, we assume that the cluster amplitudes are connected and analyze the connectivity of the \(G\) blocks. The \(G\) blocks in eqs 12 and 13 are composed of two types of terms, the so-called “direct term” and the “coupling term.” The composite quantity, \(\bar{H}_{\mu}\), is explicitly connected quantity if \(T_{\mu}\)'s are connected. Hence, the direct terms are connected. For the coupling term, we have to analyze several different aspects of the connectivity:

1. Connectivity of \(\exp(T_{\mu})|w_{\nu}\rangle\) consists of those closed components of \(\bar{H}_{\mu}\) which excites \(\phi_{\mu}\) to \(\phi_{\nu}\) and being a part of \(\bar{H}_{\mu}\) is explicitly connected. For connected \(T_{\mu}\)'s, \(\exp(T_{\mu})|w_{\nu}\rangle\) is explicitly connected. In what follows, we will henceforth denote \(\exp(T_{\mu})|w_{\nu}\rangle\) as \(X_{\mu\nu}\).

2. Connectivity of \(\exp(-T_{\mu} - T_{\nu})X_{\mu\nu}\): We consider two possible cases here: the case where \(\phi_{\mu}\) and \(\phi_{\nu}\) differ by at least one orbital (case 2a) and the case where \(\phi_{\mu}\) and \(\phi_{\nu}\) have the same orbital occupancy and either \(\phi_{\mu}\) or \(\phi_{\nu}\) differ in the spin coupling scheme of the active orbitals (case 2b).

For case 2a, the quantity \(X_{\mu\nu}\) is explicitly dependent on all the active orbitals by which \(\phi_{\mu}\) and \(\phi_{\nu}\) differ since \(X_{\mu\nu}\) contains \(W_{\mu\nu}\). Since all the CSFs in the model spaces are treated on the same footing, the functional dependence of every cluster amplitude on the active orbital labels remains the same. Hence, the difference of the amplitudes \(t_{\mu} - t_{\nu}\) inducing the same excitation depends implicitly on one or more of the active orbitals by which \(\phi_{\mu}\) and \(\phi_{\nu}\) differ. Hence, the composite \(\exp(-T_{\nu} - T_{\mu})X_{\mu\nu}\) has at least one common active orbital label shared by the two factors, and hence, the composite is connected. We also note here that our analysis subserves the case where the action of some components of \(T_{\mu}\) on \(\phi_{\mu}\) is zero in the coupling term in eq 12 because of the occupancy restrictions of some active orbitals. Clearly, the corresponding \(T_{\nu}\) involving the same label of active orbitals in creation and destruction must involve those orbitals by which \(\phi_{\mu}\) and \(\phi_{\nu}\) differ.

For case 2b, if \(\phi_{\mu}\) and \(\phi_{\nu}\) are the same, the composite in the coupling term reduces simply to \(X_{\mu\nu}\) which is obviously connected. If \(\phi_{\mu}\) and \(\phi_{\nu}\) have the same orbital occupancy but differ in their spin coupling schemes, then the quantity \(X_{\mu\nu}\) would depend...
on one or more of the same orbitals involved in the different spin couplings for $\phi_\mu$ and $\phi_\nu$. In such a situation, the difference $t_\mu - t_\nu$ will have implicit dependence on all active orbitals involved in the segments in which the spin couplings of $\phi_\mu$ and $\phi_\nu$ are different.

4.2. Connectivity of the Working Equations Involving $\{\epsilon_\mu^f\}$ and $G_\sigma$. The second level of connectivity, that of the working equation, requires more sophisticated analyses. We first note that the various ranks $n$ of $G_\sigma^{(n)}$ can contribute to a matrix element, $\langle \epsilon_\mu^f | G_\sigma^{(n)} | \epsilon_\nu^f \rangle$. Using eq 3, we may express the matrix element as expectation values with respect to $\phi_\mu$:

$$
\langle \epsilon_\mu^f | G_\sigma^{(n)} | \epsilon_\nu^f \rangle = \langle \phi_\mu | \epsilon_\mu^f \rangle \sum_n G_\sigma^{(n)} \langle \epsilon_\nu^f | \phi_\nu \rangle
$$

$$
\equiv \langle \phi_\mu | \epsilon_\mu^f \rangle \sum_n G_\sigma^{(n)} \langle \epsilon_\nu^f | \phi_\nu \rangle
$$

(52)

Using Wick’s theorem to rewrite the product of $\{\epsilon_\mu^f\}$ with those appearing in $G_\sigma^{(n)}$, it is easy to see that the only non-zero contribution to the matrix element comes from the terms which are either completely contracted or those involving unitary generators with active labels only. The latter will give rise to RDMs of various ranks dependent on the rank of the unitary generators with active labels. We note now that the set of active orbital labels destroyed by the unitary generators must be the same as those created although they are not necessarily in the same order. For example, with $\phi_\mu \equiv \phi(I,A)$, the non-zero 2-RDMs can only be $\Gamma_{13}^{(2)}$ and $\Gamma_{12}^{(2)}$. We would henceforth refer to strict index equality in the lower and upper sets, we refer to this property as “quasi-diagonality.” Hence, $\Gamma_{13}^{(2)}$ is diagonal and $\Gamma_{12}^{(2)}$ is quasi-diagonal. In our UGA-SUMRCC, all density matrix elements are either diagonal or quasi-diagonal.

For the h–p model spaces studied by us here, the non-zero 2-RDMs are not always product separable, and they may lead to disconnected pieces in various terms. The disconnected pieces appear when a part of the pairs of active orbitals appears only on the de-excitation part of the operator, $\{\epsilon_\mu^f\}$, and a part on the G block or when all the pairs of active orbitals of the RDM come from the $\{\epsilon_\mu^f\}$ only. Representative diagrams for the first case are shown in Figures 4 and 5. In a CCSD truncation scheme for an h–p quasi-complete model space, some active lines to the right may emanate from the G block and have common labels with active lines to the left which may have arisen from the projection which are the problematic situation depicted in Figures 4 and 5. Even though parts of the 2-RDM may occur on different factors ($\{\epsilon_\mu^f\}$ and $G_\sigma^{(n)}$, as in Figure 5), they are by necessity quasi-diagonal and hence connected. As a consequence, apparently cause disconnected terms when the label, $I$, and the pair, $\mu \nu$, are on different molecular fragments.

Our intention is to demonstrate that one can eliminate the disconnected terms via cumulant decomposition. We shall show that the disconnected quantities for a given working equation get canceled on invoking the working equations for other, lower rank, t-amplitudes. In order to match terms between equations, it becomes necessary to decompose higher body densities into lower body densities via a so-called cumulant decomposition.

We define the 1h density matrix element $\eta_{\mu \nu}^I$ as

$$
\eta_{\mu \nu}^I = \sum_\sigma \langle \phi_\mu | \epsilon_\mu^I | \phi_\nu \rangle = \langle \phi_\mu | \epsilon_\mu^I | \phi_\nu \rangle = 1
$$

(53)

Similarly, $\eta_{\mu \nu}^I$ is obviously equal to $\langle \phi_\mu | \epsilon_\mu^I | \phi_\nu \rangle = 1$. Using the general definition of a spin-free cumulant,

$$
\Gamma_{uvw}^{\epsilon} = \langle \phi_\mu | (E_\mu^n) \phi_\nu \rangle \langle \phi_\sigma | (E_\sigma^n) \phi_\tau \rangle - \frac{1}{2} \langle \phi_\mu | (E_\mu^n) \phi_\nu \rangle \langle \phi_\sigma | (E_\sigma^n) \phi_\tau \rangle + \Lambda_{uvw}^{\epsilon}
$$

(54)
for arbitrary active indices \( u-z \), which may be holes or particles. We then find that
\[
\Gamma_{IJ}^{IA} = -\eta_I^{J} \gamma_I^{A} + \Lambda_{IJ}^{IA} \tag{55}
\]
\[
\Gamma_{JIA}^{AI} = \frac{1}{2} \eta_I^{J} \gamma_A^{I} + \Lambda_{JIA}^{AI} \tag{56}
\]
For the \( h-p \) CSFs\( s \), it then follows that \( \Lambda_{IJ}^{IA} \) is zero and \( \Lambda_{JIA}^{AI} \) is non-zero, indicating that \( \Gamma_{JIA}^{AI} \) is not exactly factorizable into products of lower body RDMs.

To ascertain the connectivity of the working equations, by the strategy delineated in the paragraphs where the \( \eta_I^{J} \)'s are defined, let us consider the specific example of the pair of projection equations for \( \eta_I^{J} \) and \( \eta_I^{J} \), i.e., eqs 32 and 33. We note that the active label, \( I \), in the de-excitation operator, \( E_{\text{de}} \), will always contribute an RDM where \( I \) will figure in both the upper and lower indices. Among the various terms generated in the projection equations, there will be some terms containing \( \eta_I^{J} \) while the rest of the terms will contain either \( \Gamma_{IJ}^{IA} \) or \( \Gamma_{JIA}^{AI} \). The latter two can also be written in terms of factors \( \eta_I^{J} \) and \( \gamma_I^{A} \) and a cumulant, \( \Lambda \), if we use eqs 55 and 56. Thus, the entire set of projection equations can be grouped into two parts: in one, \( \eta_I^{J} \) explicitly appears, and in the other, only \( \Lambda_{IJ}^{IA} \) or \( \Lambda_{JIA}^{AI} \) but no \( \eta_I^{J} \) appears. It is then possible to rewrite eq 33 as
\[
\eta_I^{J} \left[ G_I^{\sigma} - G_{II}^{\sigma} + 2G_{II}^{\sigma} \right] + \gamma_I^{A} \left( -G_{AI}^{\sigma} + G_{II}^{\sigma} - 2G_{IA}^{\sigma} + G_{AI}^{\sigma} \right)
\]
\[\tag{term i} \]
\[\eta_I^{J} \left[ G_I^{\sigma} - G_{II}^{\sigma} + 2G_{II}^{\sigma} \right] + \gamma_I^{A} \left( -G_{AI}^{\sigma} + G_{II}^{\sigma} - 2G_{IA}^{\sigma} + G_{AI}^{\sigma} \right)
\]
\[\tag{term ii} \]
\]

We note that in term \( i \) there are several components in which the pair of lines containing label \( I \) are generated exclusively from the de-excitation operator, \( E_{\text{de}} \). These components are all disconnected, and they are all characterized by the property that the label \( I \), never appears in the associated \( G \) blocks. These disconnected entities have been shown in bold letters. It is remarkable that all the components in term \( i \) appearing in the brackets, (\( \ldots \)) in eq 57 appear in eq 32 which originates from the projection with \( E_{\text{de}} \). However, there are more components in eq 32 than what appears in term \( i \). The missing entities in term \( i \) are those in eq 32 which contain: \( a \) \( \eta_I^{J} \) and \( b \) the 2-RDMs, \( \Gamma_{IJ}^{IA} \) and \( \Gamma_{JIA}^{AI} \). These terms obviously cannot appear in term \( i \), since this would have required a cumulant decomposition of a 2-RDM, \( \Gamma_{IJ}^{IA} \), for \( a \), and 3-RDMs in eq 33 containing at least one \( \gamma_I^{A} \) in both its upper and lower indices. For \( h-p \) CSFs, \( \Gamma_{IJ}^{IA} \) and all the 3-RDMs are zero since such density matrices would have violated the exclusion principle in a \( \psi_I^{A} \) where there are only single active hole and particle occupancies labeled by \( I \) and \( A \), respectively. In order to complete the appearance of all components of eq 32 in term \( i \), we add to eq 33 all those components which contain \( \Gamma_{IJ}^{IA} \) and 3-RDMs which do not change the equation since they are all zero in a cumulant. We thus add the following sum of components, each of which is individually zero:
\[
-C_{IJ}^{\sigma} \Gamma_{IJ}^{IA} + C_{AI}^{\sigma} \Gamma_{JIA}^{AI} - C_{II}^{\sigma} \Gamma_{II}^{IA} + C_{II}^{\sigma} \Gamma_{II}^{IA} - C_{II}^{\sigma} \Gamma_{AI}^{IA} - C_{II}^{\sigma} \Gamma_{JI}^{IA}
\]
\[\tag{58} \]

Equation 33 thus becomes
\[
G_I^{\sigma} \eta_I^{J} - C_{II}^{\sigma} \eta_I^{J} - C_{II}^{\sigma} \Gamma_{II}^{IA} - C_{II}^{\sigma} \Gamma_{II}^{IA} + 2C_{II}^{\sigma} \eta_I^{J} - C_{II}^{\sigma} \Gamma_{II}^{IA}
\]
\[
-C_{II}^{\sigma} \Gamma_{II}^{IA} + C_{II}^{\sigma} \Gamma_{II}^{IA} + C_{II}^{\sigma} \Gamma_{AI}^{IA} + 2C_{II}^{\sigma} \eta_I^{J} - C_{II}^{\sigma} \Gamma_{II}^{IA}
\]
\[
-C_{II}^{\sigma} \Gamma_{II}^{IA} + C_{II}^{\sigma} \Gamma_{II}^{IA} - C_{II}^{\sigma} \Gamma_{AI}^{IA} - C_{II}^{\sigma} \Gamma_{JI}^{IA}
\]
\[
-C_{II}^{\sigma} \Gamma_{II}^{IA} + C_{II}^{\sigma} \Gamma_{II}^{IA} = 0
\]

The cumulant decomposition of the zero RDMs would generate either a product of cumulants containing an \( \eta_I^{J} \) and some 2-\( \Lambda \) or a product of 1-RDMs, one of which would be \( \eta_I^{J} \) to a 3-\( \Lambda \). In fact, the cumulant decomposition of the associated zero 2- and 3-RDMs have the expressions:
\[
\Gamma_{IJ}^{II} = 0 - \frac{1}{2} \eta_I^{J} \eta_I^{J} + \Lambda_{IJ}^{II} \tag{60}
\]
\[
\Gamma_{JII}^{JI} = 0 - \frac{1}{4} \eta_I^{J} \eta_I^{J} - \Lambda_{JII}^{JI} \tag{61}
\]
\[
\Gamma_{JII}^{IJ} = 0 - \frac{1}{2} \eta_I^{J} \eta_I^{J} - 2\eta_I^{J} \Lambda_{II}^{J} + \Lambda_{JI}^{II} + \Lambda_{IJ}^{JI} \tag{62}
\]

Using the expressions above, we can include the missing components of eq 32 in term \( i \) (to be henceforth called modified term \( i \)) and club the rest of the contribution of eq 58 into term \( ii \) (to be henceforth called modified term \( ii \)). We show explicitly only the terms containing two body \( G \) blocks to avoid complexity. The decomposition of the higher body densities using eqs 35–62 can be similarly carried out.
\[
\eta_I^{J} \left[ G_I^{\sigma} - G_{II}^{\sigma} \eta_I^{J} + G_{AI}^{\sigma} \eta_I^{J} - \frac{1}{2} G_{II}^{\sigma} \eta_I^{J} - \frac{1}{2} G_{II}^{\sigma} \eta_I^{J} \right]
\]
\[\tag{modified term i} \]
\[+ \left( \frac{1}{2} \eta_I^{J} - \eta_I^{J} - \Lambda_{II}^{J} \right) G_{AI}^{\sigma} + \left( \frac{1}{2} \eta_I^{J} + 2 \eta_I^{J} - \Lambda_{II}^{J} \right) G_{AI}^{\sigma} - \Lambda_{II}^{J} G_{AI}^{\sigma} = 0 \tag{modified term ii} \]

Owing to the validity of eq 32, the entire modified term \( i \) vanishes, making eq 33 reduce to just the modified term \( ii \) for up to two body \( G \) blocks:
\[
\left( \frac{1}{2} \eta_I^{J} - \eta_I^{J} - \Lambda_{II}^{J} \right) G_{AI}^{\sigma} + \left( \frac{1}{2} \eta_I^{J} + 2 \eta_I^{J} - \Lambda_{II}^{J} \right) G_{AI}^{\sigma} - \Lambda_{II}^{J} G_{AI}^{\sigma} = 0 \tag{64} \]

Since, 2- and 3-\( \Lambda \)'s are all size extensive quantities, eq 33 written in terms of the cumulants, \( \Lambda \), consists entirely of connected terms. Some components in the modified term \( ii \) contain only 3-\( \Lambda \)'s, and their size extensivity ensures that each such component is connected. There would also be some contribution coming from products of \( \gamma_I^{A} \) and a 2-\( \Lambda \) where the \( \gamma_I^{A} \) always occurs on the \( G \) block. Hence, these components are also connected. By an entirely similar reasoning, eq 39 involving the de-excitation operator \( E_{\text{de}} \) upon cumulant decomposition would also reduce to a set of connected components involving cumulants after invoking eq 32. Here, the roles of \( \gamma_I^{A} \) and \( \eta_I^{J} \) would be interchanged. Moreover, also for true excitations involving active orbitals (such as \( I \rightarrow a \) or \( a \rightarrow I \)), the projection equations involving an exchange spectator scattering in the de-excitation operator can be also similarly transformed into a
set of connected components containing appropriate 2-Λ’s and 3-Λ’s. The disconnected components along with several other connected components and appropriate densities vanish because of the validity of the lower body equations without the spectators. Turning now to the one-body projection equations, the uncontracted active lines in a composite may appear either entirely on the G block which is explicitly connected or one on the projection and the other on the G block. In the latter case, diagonality/quasi-diagonality of RDMs ensures that they are connected since the active line on the de-excitation operator would have one label in common with one of those occurring on the G block.

It is interesting to note that the proof of the connectivity brought to the fore the use of 2- and 3-Λ’s having indices for which the corresponding 2- and 3-Γ’s vanish due to the Pauli exclusion principle. This is clearly demonstrated in eqs 60–62 above. We may call such cumulants Exclusion Principle Violating (EPV) Λ’s. For the h−p case at the CCSD level of truncation, the connected expressions will contain up to 3-Λ’s. For higher truncation schemes, 4- and higher rank Λ’s can also appear.

The same conclusions could have been drawn by an alternative but equivalent strategy. If we include in a projection equation, such as eq 33, all the possible higher body RDMs, n > 2 in our case, and use cumulant decompositions for all of them, then, in general, all the disconnected terms cancel out because of the validity of lower body equations, leaving us with connected terms and higher body cumulants. Clearly, this method will prove to be more profitable for the general mh−np case. We note that although in the h−p model spaces, all higher body Λ’s are of the EPV type, such is not the case of a general mh−np active space. The alternative strategy introduced above becomes then much easier for the purpose of discerning connectivity.

Since the above two strategies are equivalent for proving the connectedness of the working equations, in our actual implementation we have used the parent projection equations like eq 33. Solving eqs 32 and 33 is equivalent to solving eqs 32 and 64, and the same is true for other projection equations. We must, however, bear in mind that, although the n-body RDM elements corresponding to the EPV types are zero, the corresponding n-body Λ’s are necessarily not so. Hence, in order to adopt this scheme, one must start with all possible RDMs, even those of ranks beyond the number of active electrons, in the parent projection equations. For the h−p case, the vanishing Γ’s are actually implicitly included (though only formally so).

The structure of the UGA-QFMRCC equations are exactly analogous to the UGA-SUMRCC equations where $\tilde{H}$ replaces $H$ and $\tilde{W}$ replaces $W$. Both $\tilde{H}$ and $\tilde{W}$ are connected quantities, and therefore like UGA-SUMRCC, UGA-QFMRCC also gives connected equations. Following the prescription of Mukherjee et al.,34 we can say that, as UGA-QFMRCC gives connected working equations, $\Delta E$ calculated from this theory is size intensive.

5. MOLECULAR APPLICATIONS

5.1. Computational Organizations. Three different but closely related theories have been discussed in this paper. The final working equation for obtaining the cluster amplitudes in the parent UGA-SUMRCC is eq 16.

To incorporate the lack of IN of $\Omega_p$ in the definition of $H_{\text{eff}}$ we will use the expression for $H_{\text{eff}}$ as in section 5.1 and put it back into eq 10 at each step of iteration. Using eq 15, at any iterative step $(i + 1)$, we can write:

$$\langle \phi_i | (\tilde{H}^{(0)}_{\text{eff}} + 1\tilde{W}^{(0)}_{\text{eff}}) | \phi_i \rangle = \langle \phi_i | \sum_{c} \left\{ (\exp(-T_p) \exp(T_v) - 1) \exp(-T_p) \exp(T_v) - 1 | \tilde{W}^{(0)}_{\text{eff}} | \phi_i \rangle \right\} + \langle \exp(-T_p) \exp(T_v) - 1 | W^{(0)}_{\text{eff}} | \phi_i \rangle = H_{\text{eff}}^{(i+1)}$$

where

$$W^{(0)}_{\text{eff}} = l q_{\mu} \langle \phi_i | H_{\text{eff}}^{(0)} | \phi_i \rangle$$

We start the iteration of $H_{\text{eff}}$ with the following expression:

$$H_{\text{eff}}^{(0)} = H_{\text{eff}}$$

Here, an important point to notice is that, in each step of iteration, we have chosen our $H_{\text{eff}}$ in such a manner that it corresponds to the true solution for the residue eq 15:

$$R_{\text{eff}} = 0$$

Subsequently, we will diagonalize $H_{\text{eff}}$ to get the energies for all the "$k" states.

To implement the subspace variant of the parent UGA-SUMRCC, we have separated out the blocks corresponding to linearly dependent operators. Then, the residues for each operator are computed, and iteration is performed until the residue becomes zero. The algorithm for $H_{\text{eff}}$ for the subspace variant is exactly the same as that for the parent UGA-SUMRCC.

For UGA-QFMRCC, we need to generate all possible $H_{\text{eff}}$ connected terms which is called $\tilde{H}$. Then, we should construct all possible $\Lambda_{\text{eff}}$ connected diagrams to get G blocks of which the excitation structures contribute to $S_{\mu}$’s and the closed diagrams contribute to $H_{\text{eff}}$. $S_{\mu}$’s are the differential amplitudes for the target valence sector. In our implementation technique, our goal has been to generate all diagrams possible in $H_{\text{eff}}$ connected without going through the explicit construction of all possible $\tilde{H}$’s. The scheme is as follows:

1. Write all the converged closed shell $T$’s in a file.
2. Read from the file and map the $T$’s to the indices of the model functions. Thus, now the range of the $T$ array is generalized hole–particle, with entries in valid locations and the rest zero.
3. Add the $T$ to $S_{\mu}$ and treat it as a composite array called $S_{\mu}$.
4. Evaluate all possible $H_{\text{eff}}$ connected diagrams. This gives us the correct set of required diagrams.
5. Construction of $H_{\text{eff}}$: We pick up the IP-like, EA-like, and EE-like portions from the G blocks. We also calculate the following closed diagrams where $V$ is connected to the closed shell $T$’s and $T$-like differential $S_{\mu}$’s:

$$\langle F \tilde{S}_{\mu} \rangle, \langle V S_{\mu} \rangle, \langle V S_{\mu} \rangle, \langle V T \tilde{S}_{\mu} \rangle$$

The sum of these two portions yields $H_{\text{eff}}$ at each step of iteration $(i)$. For the implementation of $S_{\mu}$, we calculate $\langle F \tilde{S}_{\mu} \rangle$, $\langle V S_{\mu} \rangle$, and $\langle V S_{\mu} \rangle$ and subtract from it the closed shell correlation energy at each iteration step. The algorithm for $H_{\text{eff}}$ is exactly the same as for the parent UGA-SUMRCC after replacing $H_{\text{eff}}$ by $H_{\text{eff}}$ and $W_{\text{eff}}$ by $W_{\text{eff}}$. Diagonalization of the final $H_{\text{eff}}$ yields excitation energies directly.

5.2. Computational Cost. The computational cost of UGA-QFMRCC must be studied stepwise. The first step is simply a CCSD calculation. The next transformation by $S_{\mu}$ involves a cost of roughly $N_{\text{dim}}$ times a CCSD computation where $N_{\text{dim}}$ is the number of model functions.
At each step, the scaling with the number of basis functions, \( N \), is dominated by the computations involving all-particle integrals, VPPPP. The number of unknowns scale as \( N^2 \), where \( n \) (generalized hole) = the number of occupied orbitals + the number of active orbitals and \( p \) (generalized particle) = the number of unoccupied orbitals + the number of active orbitals. The most expensive part of our computation is the construction of three-body G blocks which involve a cost of \( 6(n_{act})^2 \) times a CCSD computation where “nact” is the number of active orbitals and there are six possible three body structures for the G blocks given one active hole, \( I \), and one active particle, \( A \). The overall scaling behavior of our UGA-QFMRCC is in fact of the same order as those in EIP or STEOM-CC except that the STEOM-CC ignores the three-body excitation operators necessary for equivalence, of physics incorporated, with our UGA-QFMRCC as mentioned in section 3.3. This is an approximation, and such approximations are open to us as well. Due to the compact approximation, and such approximations are open to us as well. Due to the compact approximation, and such approximations are open to us as well.

### 5.3. Results and Discussions

To demonstrate the performance of “sufficiency conditions” and our new quasi-Fock formulation, we present some representative computations. Work is underway to obtain more data for a more conclusive demonstration of the strengths and weaknesses of this theory. We would like to draw the attention of the readers to the fact that some UGA-SUMRCC values presented here differ from those reported in our previous paper. This is due to some small bugs in our earlier code. The conclusions of our previous publication, however, remain unchanged. We have chosen excited states of \( \text{H}_2\text{O}, \text{HF}, \text{CH}_2, \text{BH}, \) and \( \text{CH}^+ \) for theoretical comparisons in small bases. Appropriate bar charts have been presented to compare the trends in results for the parent UGA-SUMRCC (scheme P) and its variant (scheme S) where sufficiency conditions have been employed. Tables are presented to demonstrate the better performance of UGA-QFMRCC in comparison with EOMCC and the comparable performance of UGA-QFMRCC and the parent UGA-SUMRCC. Subsequently, we present excitation energies in comparison with experimental results for \( \text{H}_2\text{O} \) and \( \text{C}_2\text{H}_2 \). All unreferenced results have been computed by us using GAMESS US-2007 or -2010. Results of EOM-CCSD for triplet states have been obtained using DALTON 2.0.

#### Molecular Specifications

In the present section, we describe the molecular geometry, active spaces, and basis sets considered for our computations. The geometries for comparison with experimental results are mentioned as footnotes to the corresponding tables. The \( \text{H}_2\text{O} \) molecule has been studied in DZV and cc-PVnZ \((n = D,T,Q)\) bases at the ground state equilibrium geometry: \( O(0, 0, 0), H(0, \pm 0.751155, -0.581606) \) in Å. The model space of \( \text{H}_2\text{O} \) contains \( (3a_1, 1b_1) \) orbitals from the occupied level and \( (4a_1, 2b_1) \) orbitals from the unoccupied level in all of our applications in the present paper.

The excitation energies for the singlet and triplet states of \( \text{HF} \) have been computed using the DZV and cc-PVnZ \((n = D,T,Q)\) bases at a bond length of 1.40 au. For \( \text{HF} \), we have considered the two lowest energy degenerate functions of \( B1 \) and \( B2 \) symmetry in our model space.

The coordinates for \( \text{CH}_2 \) have been taken as \( \text{C}(0, 0, 0), \text{H}(0, \pm 0.87251610, -0.67314164) \) in Å. For this molecule, our choice of model space consists of the \( 3a_1 \) orbital from the occupied set of orbitals and \( (4a_1, 1b_2) \) from the unoccupied orbitals.

Computations for \( \text{BH} \) have been carried out at a bond length of 2.3289 au using cc-PVnZ \((n = D,T,Q)\) bases. We have chosen the \( (3a_1, 1b_1) \) orbital from the occupied set of orbitals and \( (1b_2, 2b_2) \) orbitals from the virtual set for the construction of our model space.

\( \text{CH}^+ \) has been treated at its equilibrium geometry of 2.137280 au. The bases we have used for this computation consist of the \( 3a_1 \) orbital from the occupied set of orbitals and \( (4a_1, 1b_2) \) from the unoccupied orbitals.

#### Table 3. Scheme S – Scheme P in mH: Difference between Use of Sufficiency Conditions and Use of Linearly Independent Manifold of Operators

| molecule | state | cc-pVDZ | cc-pVTZ | cc-pVQZ |
|----------|-------|---------|---------|---------|
| HF       | \( ^1\text{II} \) | -1.776  | -1.889  | -1.992  |
|          | \( ^3\text{II} \) | -0.959  | -1.24   | -1.258  |
| \( \text{H}_2\text{O} \) | \( ^1\text{B}_1 \) | -2.751  | -2.638  | -2.656  |
|          | \( ^3\text{A}_1 \) | -1.689  | -1.888  | -2.206  |
|          | \( ^1\text{A}_1 \) | -2.197  | -1.792  | -1.639  |
|          | \( ^1\text{B}_2 \) | -2.234  | -2.025  | -1.977  |
|          | \( ^3\text{A}_1 \) | -0.959  | -1.009  | -1.049  |
|          | \( ^3\text{A}_1 \) | 0.206   | -0.077  | -0.413  |
|          | \( ^3\text{A}_1 \) | -0.336  | -0.343  | -0.446  |
|          | \( ^1\text{B}_2 \) | 0.111   | -0.099  | -0.332  |
| \( \text{CH}_2 \) | \( ^1\text{B}_1 \) | 0.887   | 0.108   | 0.212   |
|          | \( ^3\text{B}_1 \) | 1.668   | 0.529   | 0.316   |
| \( \text{CH}^+ \) | \( ^1\text{II} \) | 0.346   | 0.858   | 2.653   |
|          | \( ^3\text{II} \) | 0.933   | 1.016   | 1.77    |

#### Table 4. Statistical Data for Percent Error of S vs P

|            | \( [(\text{abs(S - P)})/\text{P}] \times 100 \) | \( [(\text{S - P})/\text{P}] \times 100 \) |
|------------|-----------------------------------------------|-----------------------------------------------|
| mean       | 0.00175                                       | 0.00078                                       |
| SD         | 0.00143                                       | 0.00214                                       |
| max diff   | 0.00699                                       | 0.00362                                       |
| min diff   | 0.00010                                       | -0.00699                                      |

**Figure 7.** Bar chart showing absolute percent error of scheme S vs scheme P in UGA-SUMRCC.
are cc-PVnZ (n = D,T,Q). Here, our choice of model space contains two degenerate function of \( B_1 \) and \( B_2 \) symmetry.

**Use of Nonredundant vs Redundant Excitations.** The scheme using sufficiency equations (denoted as scheme S) is tested for excited states of several molecules. On comparing with the full scheme (denoted as scheme P) where only a linearly independent excitation space is used, it appears that consistency is lacking for scheme S across different molecules. However, error ranges are not very high. A further approximation where three-body G blocks with double-exchange spectators whose operator structure corresponds to three body T’s as per our policy are neglected is also explored. This scheme is called scheme S’. The performance of this approximation in scheme S is found to follow the trend of performance of scheme P which involves a similar approximation in scheme P. We may thus independently analyze the issue of importance of higher body G blocks appearing at higher orders of perturbation and the use of sufficiency conditions in the working equations. As demonstrated in our previous paper, the contribution of four-body blocks is on the order of tenths of a mH and may be neglected for preliminary investigations. The scheme denoted as scheme P2 in our previous paper is denoted as scheme P in this paper as G blocks up to three-body have only been considered for all computations.

To represent the efficacy of the sufficiency variant of UGA-SUMRCC in comparison with the parent theory, we resort to the following sets of data/charts:

1. Table 3 shows the difference in energy between the two variants along the cc-PVnZ series of basis (where \( n = D,T,Q \)) separately for excited states of \( \text{H}_2\text{O}, \text{HF}, \text{CH}_2\text{O}, \text{BH}, \text{CH}^+ \) molecules. Several states of both singlet and triplet multiplicities have been considered. Clearly, we expect a range of difference values across different bases and states, but this should be small for the viability of scheme S. Since the state energies for different molecules are extensive quantities, we have compared the percent deviation of S vs P in this reasonably large sample space of 42 data points. The bar chart in Figure 7 pictorially represents these data. Statistical data like mean, absolute mean, and standard deviation from absolute mean have been extracted to inspect the systematism (please refer to Table 4).

2. To investigate how both the variants behave with respect to the FCI energy (where available), we have presented tables where deviation from FCI for each method has been provided (Tables 5–10).

3. To analyze the change in error with a systematic increase in basis size, we compare the standard deviation of the percent gain in correlation energy from cc-pVDZ to cc-pVTZ and from cc-pVTZ to cc-pVQZ across our sample space separately for the full projection scheme (P) and the variant using sufficiency (S).

The bar chart in Figure 7 for different molecules shows very consistent results. A few outliers are the \( ^1A_2 \) and \( ^1B_2 \) states of \( \text{H}_2\text{O} \) in the cc-pVDZ basis, which are of opposite trend from rest of the bases (please refer to Table 3).
Table 13. Triplet Excitation Energies (\(\Delta E\)) of \(\text{H}_2\) in DZV Basis

| method            | \(^3\Pi\) M-FCI (mH) | \(^1\Pi\) M-FCI (mH) | \(^3\Sigma\) M-FCI (mH) | \(^1\Sigma\) M-FCI (mH) |
|-------------------|----------------------|----------------------|-------------------------|-------------------------|

Though, in an absolute sense, these differences are not very large. The reason may lie in some sort of inadequate description of these states in cc-pVDZ basis. We have also seen that the difference values may be positive or negative, which indicates that both ordinary mean and absolute mean would be necessary to get a feeling of the performance of sufficiency equations vs the full scheme. The signed mean of all the percent difference values is 0.00078%, i.e., a positive number, suggesting that, statistically speaking, the sufficiency results are lower than the full projection scheme. The reason may be attributed to the greater number of degrees of freedom in the sufficient equations. The percent absolute mean value, an important qualifier for our set of data, is 0.00175%.

certainly not a very large value. The maximum and minimum values and standard deviations of differences are also reasonable quantities (please refer to Table 4). From this analysis, we may conclude that the dispersion of data for sufficiency as against projection is not very wayward.

Our comparison against FCI shows that the full scheme performs pretty well in all cases. Keeping in mind that these are solutions of nonlinear equations, the errors may be both positive and negative. We see that the full scheme gives results mostly above FCI. The sufficiency variant of the parent theory performs somewhat erratically in the sense that it may overshoot or undershoot the FCI values. Though this nature is not observed in the parent theory, when the comparison is done along different states of a particular molecule, the variant using sufficiency is lacking this quality. The absolute percent difference values, on the other hand, in Figure 7 clearly show that they not very large. The primed schemes wherein certain three-body blocks which occur at higher orders of perturbation have been excluded are not quite reliable, indicating that the excluded blocks often play a significant role in the description of excited states.

In the third set of comparisons, we have seen a consistent change in percent correlation with an increase in basis size for our theory (please refer to Table 11). There are no sudden jumps in error as evidenced by the small standard deviation. This is true for both schemes and hence validates our expectation that there are no limitations in the description of excited states for our theory with increasing basis size. The mean and standard deviations are very similar for schemes P and S, indicating that invoking sufficiency does not affect the change of energy with increasing basis size.

**Quasi-Fock MRCC.** The trends for accuracy as evidenced by difference from FCI values are the same for UGA-QFMRCC and the parent UGA-SUMRCC. Results show a difference on the order of mH. The UGA-QFMRCC predicts excitation energies which are consistently lower than the corresponding value obtained by taking an explicit difference of UGA-SUMRCC excited state energy and CCSD ground state energy (Tables 12–19). Due to the unitary group adapted description of our target state and use of projection equations, higher body G blocks (three and four body) are involved. Thus, although the description of the ground and excited state are well-balanced in terms of operators, there exists a discrepancy at the block level. The use of projection equations necessitates the involvement of certain three and four body blocks which correspond to triples and quadruples as in CCSDtq. These could implicitly contribute to an overcorrelation of the excited state as against the ground state, which is correlated at the purely CCSD level. The more or less consistent improvement over EOM-CCSD is most likely due to the greater incorporation of orbital relaxation.

6. SUMMARY AND FUTURE OUTLOOK

In this paper, an extensive analysis of several different aspects of UGA-SUMRCC has been undertaken. Detailed proof of size extensivity of the theory for hole–particle model spaces has been presented, using cumulant decomposition of reduced density matrices (RDM). This had not been previously discussed in the earlier paper of ours. A numerical study of the use of a redundant set of linearly dependent excitation operators versus the use of linearly independent combinations of excitation operators has also been undertaken. The former has been found to have mixed performance relative to the latter for the different molecular states studied by us. A systematic study of the performance of the variants of UGA-SUMRCC with increasing basis size showed that no untoward behavior occurs with increasing basis size. An extension of the UGA-SUMRCC for the direct calculation of energy differences has also been developed, along with numerical applications. We have called this method UGA-Quasi-Fock MRCC theory. This has been found to perform satisfactorily. The insight it provides into the nature of excited state physics incorporated into our formulation is significantly enlightening. We find that both the UGA-SUMRCC and UGA-QFMRCC perform satisfactorily, showing a consistent improvement over the popular and widely used EOM-CCSD theory.

Our formulation is well suited for extension to higher valence sectors, which we hope to undertake in the near future to increase the realm of applicability. Like all the effective Hamiltonian formalisms, our theories also suffer from the problem of intruders unless we confine ourselves to the low energy excited states only. However, this difficulty may be bypassed by casting the equations as a dressed CI using an Eigenvalue Independent Partitioning (EIP)/intermediate Hamiltonian technique. We hope to work on this too in the near future.
