Fun with New Gauge Bosons at 100 TeV

Thomas G. Rizzo

Abstract

The production of new gauge bosons is a standard benchmark for the exploration of the physics capabilities of future colliders. The $\sqrt{s} = 100$ TeV Future Hadron Collider will make a major step in our ability to search for and explore the properties of such new states. In this paper, employing traditional models to make contact with the past and more recent literature, we not only establish in detail the discovery and exclusion reaches for both the $Z'$ and $W'$ within these models but, more importantly, we also examine the capability of the FHC to extract information relevant for the determination of the couplings of the $Z'$ to the fermions of the Standard Model as well as the helicity of the corresponding $W'$ couplings. This is a necessary first step in determining the nature of the underlying theory which gave rise to these states.

1 Introduction and Background

Interest is growing in the physics of a possible Future Hadron Collider (FHC) which will take over the Energy Frontier sometime after the running of the HL-LHC been has completed [1]. CERN has already begun a 5-year study to investigate this possibility [2]. Presently, the FHC is currently envisioned as having a center-of-mass energy of $\sqrt{s} \simeq 100$ TeV and having the capability to accumulate integrated luminosities of order $\sim 1$ ab$^{-1}$ or greater [1].

As is well-known, the LHC has/had ‘the origin of electroweak symmetry breaking in the Standard Model’ as a known ‘no-loose’ physics target to set its energy scale. Clearly, with the discovery of the Higgs boson in 2012, the LHC has already been quite successful in this regard. The 100 TeV energy for the FHC, on the otherhand, represents an educated extrapolation of what might be possible given foreseeable technological improvements without incurring ‘prohibitive’ costs while simultaneously allowing for the opening up of potential new physics thresholds. The FHC is thus truly a machine of exploration as were the accelerators of earlier

---

[1] Interestingly, this energy represents as large of a step above that of the LHC as the LHC was above the Tevatron.
generations. Of course, in a more general context, the physics associated with such higher energy hadron colliders beyond the LHC has been frequently discussed from time to time over the past two decades \[3\] since the cancellation of the SSC.

One of the historic and standard new physics benchmarks that is always employed in the study of the potential capabilities of future colliders is the production and examination of new neutral ($Z'$) and charged ($W'$) gauge bosons \[4\] the reason being that they are a relatively common occurrence in many beyond the Standard Model (BSM) scenarios and they (usually) have relatively clean leptonic signatures. This may be of particular relevance at a high luminosity $\sqrt{s} = 100$ TeV machine where one can presently only guess at the difficulty of making measurements within this challenging hadronic environment. While previous works \[5\] have provided us with some idea as to what to expect as far as the discovery potential for $Z', W'$ might be at the FHC, here we wish to go somewhat further in both the quantification of these results and to address the question of how well such new states might be studied assuming that they are indeed discovered. In order to make direct contact with many past studies \[4-6\] we will restrict ourselves to the somewhat traditional set of BSM models containing $Z'/W'$ considered there. We remind the reader that this does not in any way exhaust the range of possibilities for such new states but it does give us a respectable range of predictions to examine for what one might expect at 100 TeV. Here we will also restrict our attention to the relatively safe final states which employ at least one (very) high $p_t$ lepton trigger due to the unknown nature of the hadronic environment and pile-up conditions the detectors may have to deal with at 100 TeV as mentioned earlier. Furthermore, we will concentrate mostly on electron final states as muon $p_t$ resolution for (many) multi-TeV muons is likely to be difficult with the typical magnetic fields that are currently available given finite detector size even when we allow for factors of two scaling in both these quantities.

Present measurements by both ATLAS \[7, 8\] and CMS \[9, 10\] at $\sqrt{s} = 8$ TeV with $\sim 20$ fb$^{-1}$ of integrated luminosity can only provide lower bounds on the masses of possible new $Z', W'$ states. For example, if these states have couplings identical to those of the corresponding SM gauge bosons \(i.e.,\) the so-called SSM ‘model’) their masses must exceed 2.96 and 3.35 TeV, respectively. Of course for other types of couplings, quite different, generally somewhat weaker results are obtained as in the case of an $E_6$-inspired $Z'$ \[11\]. Eventually, at the 14 TeV HL-LHC, search sensitivities for the same $Z'_{SSM}$ and $W'_{SSM}$ states may be as large as $\sim 6-8$ TeV \[12\] depending upon whether they are discovered or excluded. In what follows we will generally assume that the masses of these new states are beyond the reach of the HL-LHC at least to study in any detail even if they were to be in fact discovered there.

In the analysis below we will examine not only the discovery and exclusion rates for these new states at 100 TeV but also survey how data obtainable by experiments at the FHC may be used to determine their detailed properties through a number of different observables. This survey is not meant to be either exhaustive or conclusive but only to provide a first glimpse at what some of these possibilities might be based on earlier studies performed for
other hadron colliders. Much work will still be needed to examine the feasibility of the use of the many observables discussed below for the study of new gauge bosons at the FHC. We first consider new $Z'$ gauge bosons in the next Section and then turn our attention to the $W'$ case in Section 3. Section 4 contains a discussion and our conclusions. The Appendix considers the case of SSM $Z'$ and $W'$ gauge bosons but with non-SSM coupling strengths.

2 New $Z'$ Bosons

The first issue we address is the obvious one: what is the mass reach for $Z'$ gauge boson discovery or exclusion at $\sqrt{s} = 100$ TeV? The usual approach as performed at the LHC has two components: (i) compare the expected opposite-sign dilepton invariant mass distribution with the SM expectations and look for excesses at high mass and then either claim an excess or set a limit (ii) compare the expected number of (excess?) dilepton events with the the narrow-width approximation (NWA) cross section (times leptonic branching fraction) for the the $Z'$ within a given BSM model. To perform the corresponding calculations here for the FHC we will assume a detector below with a lepton rapidity coverage ($|\eta_{\ell}| \leq 2.5$) and electron EM energy resolution similar to that of the present ATLAS detector and, to be specific, we will make use of the default NLO CTEQ6.6 pdfs and scale the relevant cross sections employing NLO K-factors when obtaining our numerical results. $Z'$ (and correspondingly $W'$ below) partial widths will be calculated including NLO and partial NNLO QCD corrections as well as the corresponding NLO QED corrections. As a final comment, we note that these calculations will be performed using a fixed-width prescription for the $Z'$ but one can easily check that identical results are obtained using the running-width instead given the resulting level of statistics.

To begin our analysis it is instructive to examine the resonance signal structure for $Z'$ production in the Drell-Yan dielectron mass distribution at 100 TeV. A first example of this is shown in Figs. 1 and 2 which show the Drell-Yan mass distributions for several different $Z'$ models assuming a mass of either 16 or 21 TeV along with the associated SM backgrounds taking an integrated luminosity of 1 ab$^{-1}$. From the upper panel of Fig. 1 it is fairly obvious that for a mass of 16 TeV with this luminosity all of these models predict an easily visible signal above the SM background. In the lower panel we see how the signals will respond if the dilepton mass resolution were to become worse by a factor of 2; clearly all the states still remain easily visible. It is important to note that in most of these models the width to mass ratio of the $Z'$ is quite comparable to and frequently less than these resolutions which imply that it is the resolution itself that often controls the ‘lineshape’ and not the actual $Z'$ width. On the other hand, when the $Z'$ mass is increased to 21 TeV (not a randomly

---

2 We will not consider the interesting possibility to study this new physics with polarized proton beams here.

3 We remind the reader that there are presently significant uncertainties in extrapolating the currently available pdfs up to 100 TeV.

4 In what follows we will always assume that any new gauge bosons are un-mixed with their SM counterparts and that they decay only into the known SM states in obtaining all numerical results.
Table 1: $\sigma B_{\ell}$ in ab at 100 TeV for different $Z'$ model masses are shown in the left three columns employing the NWA. Discovery and exclusion reaches in TeV for 1 ab$^{-1}$ of integrated luminosity are visible in the two right-hand columns. Increasing the integrated luminosity to 3 ab$^{-1}$ will raise the reach mass values in all cases by $\simeq 2.9$ TeV.

| Model | 10 TeV | 15 TeV | 20 TeV | Disc. | Excl. |
|-------|--------|--------|--------|-------|-------|
| SSM   | 2021.  | 232.6  | 36.65  | 23.8  | 27.3  |

Table 1: $\sigma B_{\ell}$ in ab at 100 TeV for different $Z'$ model masses are shown in the left three columns employing the NWA. Discovery and exclusion reaches in TeV for 1 ab$^{-1}$ of integrated luminosity are visible in the two right-hand columns. Increasing the integrated luminosity to 3 ab$^{-1}$ will raise the reach mass values in all cases by $\simeq 2.9$ TeV.
Figure 1: Top: Histograms of the Drell-Yan mass distribution for the production of a 16 TeV $Z'$ at the FHC: the red (green, blue, magenta, cyan) histogram is for the SSM (Left-Right Model (LRM) \[16\], $E_6$ models $\psi$, $\chi$ and $\eta$, respectively). The yellow histogram is the SM background. ATLAS-type acceptances and smearings have been assumed. Bottom: Same as the upper panel but now assuming a factor of 2 worse dielectron mass resolution; note the change in the size of the binning here.
Figure 2: Same as the previous Figure but now for a $Z'$ mass of 21 TeV.
Figure 3: $\sigma B_\ell$ in fb as a function of the $Z'$ mass in TeV at $\sqrt{s} = 100(80)$ TeV calculated in the NWA in the top(bottom) panel. The color codes for the curves shown here are the same as in the previous Figure but now also include (black solid) that for $E_6$ model I.
to which the $Z'$ belongs commutes with the SM $SU(2)_L$ group factor, which is true for GUT groups such as the LRM and $E_6$, there remain only 5 such parameters corresponding to the couplings of the $Z'$ to $u_L = d_L$, $\nu_L = e_L$, and $(u,d,e)_R$. Note that within these GUT-like frameworks any gauge anomalies that may apparently exist are canceled by the presence of additional fermions which are either SM singlets or are vector-like with respect to the SM interactions. As noted above, when making the numerical calculations that we will present below it will always be assumed that all such fields are kinematically inaccessible in the decays of the new gauge bosons that we consider. However, since such states might participate in $Z', W'$ decays, using observables that are sensitive to the existence of these states in order to identify the $Z'$ or $W'$ themselves is problematic and may lead to the wrong conclusions [4]. Interestingly, we note that reducing the leptonic branching fraction by a factor of two due to new open channels will result in a reduction of the discovery and exclusion reaches by roughly $\simeq 2$ TeV in all cases.

It should be noted here for completeness that the observation of a new high mass resonance in the opposite-sign dilepton channel does not necessarily imply that a $Z'$ has been discovered. For example, we have not discussed here the importance of the determination of the resonance’s spin via the leptonic angular distribution [4]. One could imagine that such a resonance could be spin-2 (e.g., a Kaluza-Klein graviton) or even spin-0 (e.g., an R-Parity violating sneutrino) so the discovery of a spin-1 state is assumed in the discussion that follows.

Clearly the production cross section times leptonic branching fraction of the $Z'$ itself is a potentially interesting observable for determining fermionic couplings. As we saw in Table 1 above, these cross sections vary substantially from model to model, even within the $E_6$ scenario itself as is shown in Fig. 4 where a variation of more than a factor of 3 is observed. Trivially, this observable on its own is obviously sensitive to variations in the different coupling parameters. However, the value of the leptonic branching fraction employed to obtain these results assumes that the $Z'$ can decay to only SM particles. Thus, strictly speaking, we cannot use this observable (alone) to obtain determinations of the $Z'$ couplings. Of course, as has long been known, ratios of such cross section times branching fractions are insensitive to any additional decay modes that the $Z'$ may have and we will make use of this result below.

With this issue in mind and using the same production channel (dileptons) as for discovery there are other observables that one can use to obtain coupling information that are insensitive to any potential additional $Z'$ decay models. The most obvious one is obtained by just rescaling the overall signal rate by the extracted width of the $Z'$ resonance. In the NWA we see this quantity is just the product $\sigma B\Gamma_{Z'}$ which is clearly independent of whether or not additional $Z'$ decay modes are present (since the product $B\Gamma_{Z'}$ is just the leptonic width of the $Z'$) and this remains true to a good approximation even when a more detailed calculation is performed. Results for this quantity using the NWA can be seen in Table 2 and in Fig. 5. This Figure shows the NWA evaluation of this quantity in the $E_6$ case.

\footnote{Of course the SSM does not fall in this class as it is merely used as a benchmark so that there are still 7 distinct couplings in this case as for the SM $Z$ (by definition).}
Figure 4: $\sigma B_\ell$ in fb as a function on the $E_6$ mixing angle $\theta$. In the top panel we see the result for masses (from top to bottom) of 5, 7.5, 10, 12.5, 15, 20 and 25 TeV, respectively. In the lower panel we see the magnified result for the case of $M=15$ TeV.
Table 2: $\sigma B_t \Gamma_{Z'}$ in units of $\text{ab-GeV}$ at $\sqrt{s} = 100$ TeV for different $Z'$ model masses employing the NWA.

| Model | 10 TeV | 15 TeV | 20 TeV |
|-------|--------|--------|--------|
| SSM   | 0.6108 | 0.1054 | 0.0221 |
| LRM   | 0.2815 | 0.0487 | 0.0102 |
| $\psi$| 0.0308 | 0.0053 | 0.0011 |
| $\chi$| 0.1615 | 0.0281 | 0.0059 |
| $\eta$| 0.0404 | 0.0069 | 0.0015 |
| $I$   | 0.1326 | 0.0231 | 0.0049 |

demonstrating its respectable coupling sensitivity, varying by a factor of $\simeq 6$ just within this model framework while the Table shows variations as large as a factor of $\simeq 15$. To use this quantity we need to extract not only the production cross section in the leptonic channel but also we need to determine the $Z'$ width by a de-convolution of the mass resolution in the peak region. An early ATLAS study of this quantity for the 14 TeV LHC [17] for 10 fb$^{-1}$ of simulated data suggests that this may be possible with slightly larger than statistical errors, e.g., $\simeq 1.3/\sqrt{N}$. Clearly further study of this quantity at higher energies and masses would be valuable.

Perhaps the most well known example of a coupling-sensitive observable that makes use of the dilepton discovery channel is $A_{FB}$ which can be obtained in principle from the lepton’s angular distribution. In the $Z'$ rest frame, with $z = \cos \theta^*$ being defined between the initial quark, $q$, and outgoing $l^-$ direction this distribution is given by $\sim 1 + z^2 + 8 A_{FB} z/3$. Fig. 6 shows two very idealized examples for these distributions (before any acceptance corrections, etc) assuming 300 dilepton events are observed. These figures demonstrate the typical level of statistics required to determine $A_{FB}$ with some reliability (given the typical asymmetries predicted in many models) in an idealized situation. To get closer to reality two additional requirements are obvious: (i) an acceptance correction needs to be applied to account for the cut of $|\eta_l| < 2.5$ on the lepton rapidity. This effectively reduces the the number of events at large values of $|z|$ thus reducing the overall sensitivity to any non-zero asymmetry. Even more importantly, (ii) a correction must be applied to identify which direction along the collision axis is to be identified with that of the initial $q$. A first approximation for this (that can be later more fully performed by Monte Carlo) is to note that, most of the time, due to the pdfs, the $q$ direction can be identified with boost direction of the $Z'$ which can be easily reconstructed. This requires a minimum cut on $|y_{Z'}|$, here chosen to be $> 0.3$ for numerical purposes, which, at the very least will further reduce the level of statistics. This cut becomes quite significant as the $Z'$ mass increases and the $Z'$ rapidity becomes ever more central with the maximum $Z'$ boost being $y_{max} = \log(\sqrt{s}/M_{Z'}) \simeq 2.30(1.90, 1.61)$ for masses of 10(15, 20) TeV at $\sqrt{s} = 100$ TeV.

This discussion informs us that a reasonable level of statistics, roughly on the order of $\sim 300$ signal events, will be required for a respectable determination of $A_{FB}$. Such event rates are achievable for $Z'$ masses roughly $\simeq 6$ TeV below the mass where discovery is possible.
Figure 5: $\sigma B^\ell \Gamma_{Z'}$ at 100 TeV in units of ab-GeV as a function on the $E_6$ mixing angle $\theta$. The curves are labeled as in the previous Figure.
Figure 6: Idealized normalized leptonic angular distributions assuming 300 observed events assuming $A_{FB} = -0.2(0.1)$ in the top(bottom) panel. Only statistical errors are shown.
| Model | 5 TeV | 10 TeV | 15 TeV | 20 TeV |
|-------|------|------|------|------|
| SSM   | 0.0363 | 0.0472 | 0.0491 | 0.0485 |
| LRM   | 0.0795 | 0.1056 | 0.1113 | 0.1115 |

| I     | -0.2292 | -0.3339 | -0.3966 | -0.4437 |

**Table 3:** $A_{FB}$ at $\sqrt{s} = 100$ TeV for different $Z'$ model masses employing the NWA and the rapidity cuts as described in the text.

This implies, e.g., that for an SSM $Z'$ a reliable value of $A_{FB}$ is not obtainable if the mass is in excess of 18 TeV or so unless luminosities in excess of the canonical 1 ab$^{-1}$ value that we have assumed here are achievable.

Of course, if $A_{FB}$ is indeed measurable with some precision it will provide the SM fermion coupling sensitivity as advertised as can be seen in the upper panel of Fig. 7 and in Table 3 both of which were obtained in the NWA. Here we see not only the model dependence of $A_{FB}$ but also its dependence on the $Z'$ mass due to the evolution of the pdfs as well as the rapidity requirements due to the kinematically induced changes in the the corresponding distributions. A possible advantage of going beyond the NWA is that $A_{FB}$ as a function of the dilepton mass can be examined providing additional information about the interference between the SM and $Z'$ exchanges [4]. Fig. 8 shows that in a more realistic situation where the NWA is not employed, getting a good handle on $A_{FB}$ in narrow mass bins (outside of the one with the resonance peak itself) will be difficult even for $Z'$ masses as low as 12 TeV and even with luminosities of 5 ab$^{-1}$ as shown here. The bin to bin fluctuations are seem to be far dominant here due to the limited statistics. Thus only the coarse-grained invariant mass dependence of $A_{FB}$ will likely be of any use away from the pole. Fig. 9 shows that this is indeed the case, making use of fixed 500 GeV wide bins over which $A_{FB}$ is averaged. Here we clearly see that measurements of $A_{FB}$ in the SM-$Z'$ interference regime will be useful in coupling extraction provided sufficient luminosity is available to reduce the statistical errors. We note that in the lower panel of Fig. 8 which examines just the bins surrounding and containing the $Z'$ mass peak, that the NWA provides a reasonable estimate of the actual asymmetry near the pole. Note that once we have passed the pole statistics plummets and we gain little more information.

A third possible observable employing the dilepton final state is to construct rapidity ratio [4] in the region near the $Z'$ pole which is define via:

$$r_y = \frac{\int_{y_1}^{y_1} \frac{d\sigma}{dy} dy}{\left[ \int_{y_1}^{Y_y} \frac{d\sigma}{dy} dy + \int_{-y_1}^{-y_1} \frac{d\sigma}{dy} dy \right]}.$$  \hspace{1cm} (1)

This ratio essentially measures the fraction of central rapidity events which depends upon the relative weighting of the $u\bar{u}$ and $d\bar{d}$ pdfs with the cut $y_1$ defining the central region boundary.
Figure 7: NWA values of $A_{FB}$ in $E_6$ models as above for $Z'$ masses of 5, 10, 15 and 20 TeV (from top to bottom) after the rapidity cuts described in the text have been applied.
Figure 8: Dilepton invariant mass dependence of $A_{FB}$, subject to the cuts described in the text assuming a $Z'$ mass of 12 TeV and an integrated luminosity of 5 ab$^{-1}$. (Top) For a range of narrow invariant mass bins for the SSM(red) and LRM(blue) scenarios. (Bottom) For the SSM(red), LRM(blue), $\psi$(green), $\chi$(black) and $\eta$(cyan) models but now tightly focused on the invariant mass region surrounding the 12.4 TeV resonance region.
Figure 9: Dilepton invariant mass dependence of $A_{FB}$, subject to the cuts described in the text assuming a $Z'$ mass of 12 TeV and an integrated luminosity of 5 ab$^1$ integrated over 500 GeV wide mass bins to gain statistics. These are shown for (Top) the SSM(red), LRM(blue), $\psi$(green), (Bottom) $\chi$(magenta), $\eta$(cyan) and $I$ models.
Table 4: $r_y$ at $\sqrt{s} = 100$ TeV for different $Z'$ model masses employing the NWA and the rapidity cuts as described in the text.

| Model | 5 TeV | 10 TeV | 15 TeV | 20 TeV |
|-------|-------|--------|--------|--------|
| SSM   | 0.725 | 1.060  | 1.655  | 2.561  |
| LRM   | 0.740 | 1.096  | 1.713  | 2.625  |
| $\psi$ | 0.712 | 1.033  | 1.612  | 2.513  |
| $\chi$ | 0.783 | 1.206  | 1.905  | 2.851  |
| $\eta$ | 0.691 | 0.987  | 1.542  | 2.438  |
| I     | 0.825 | 1.328  | 2.142  | 3.153  |

and $Y = \min(2.5, y_{max})$. Note that as the $Z'$ mass increases for fixed $y_1$ the ratio $r_y$ will grow significantly due to the kinematic constraints arising from $y_{max}$. For demonstration purposes, here we will assume $y_1 = 0.5$ but this value generally needs to be re-optimized for different values of the $Z'$ mass. To examine the $r_y$ sensitivity to $Z'$ coupling variations we present the results shown in Table 4 and Fig. 11 for various models and which employ the NWA. For low $Z'$ masses the sensitivity is seen to be rather modest but increases significantly as the mass increases. Of course the available statistics to make this measurement decreases significantly for large masses and the statistical error on $r_y$ scales as $\sim (1 + r_y)(r_y/N)^{1/2}$ where $N$ is the total number of relevant signal events. For example, this would imply, for a $Z'$ with a mass of 10 TeV, that $\delta r_y = 0.027(0.038, 0.046)$ for the SSM($\chi, \eta$) case assuming a luminosity of 5 ab$^{-1}$ whereas for a mass of 15 TeV we would instead obtain the values $\delta r_y = 0.129(0.189, 0.215)$, respectively. Clearly there is some rather modest model sensitivity obtainable using this observable for relatively low $Z'$ masses. We could try getting more information by looking at $r_y$ as a function of the dilepton invariant mass, $r_y(M)$, but as Fig. 10 shows the overall behavior of this quantity is much more driven by the the shrinking rapidity range (for a fixed $y_1$ cut) as $M$ increases than by the $Z'$ couplings.

As a last possibility worth mentioning, one can imagine employing the ditau decay mode of the $Z'$ and then measure the polarization of the $\tau$'s themselves [4]. The lower panel in Fig. 11 shows that this quantity, if measurable, has quite significant coupling sensitivity. However, at the 100 TeV FHC, performing this measurement using, e.g., the $\pi$ or $\rho$ decays from the $\tau$ may prove to be rather difficult given the rather complex hadronic environment one might naively expect. However this is certainly worthy of further study.

As discussed above, here we have been limiting our discussion to signals employing leptonic triggers so that we will not consider modes such as $Z' \to b\bar{b}$. Thus we are led to consider 3-body decays involving leptons such as $Z' \to l^+l^-Z$ and $Z' \to l^+\nu W^+$ and, in particular the ratios of the partial widths for these reactions relative to that for $Z \to l^+l^-$ denoted as $r_{lZ}$ and $r_{lW}$ in the literature [4]. As discussed above, we employ these ratios to remove the potential sensitivity to non-SM $Z'$ decays. Assuming that the $Z'W^+W^-$ coupling is absent at tree-level (which it is in the GUT-type models under consideration in the absence of $Z - Z'$ mixing which we assume here), these processes occur by the emission of $W/Z$ gauge bosons from one of the lepton legs in ordinary $Z'$ dilepton decays. At the LHC,
Figure 10: The invariant mass dependence of $r_y$, subject to the cuts described in the text assuming a $Z'$ mass of 12 TeV and an integrated luminosity of 5 ab$^1$ integrated over 500 GeV wide mass bins. These are shown for the SSM(red), LRM(blue), $\psi$(green), $\chi$(magenta), $\eta$(cyan) and I models.
Figure 11: (Top) NWA values of $r_y$ in $E_6$ models as above for $Z'$ masses of 5, 10, 15 and 20 TeV (from bottom to top) after the rapidity cuts as described in the text have been applied. (Bottom) Tau polarization asymmetry in the NWA for $E_6$ type models.
for $Z'$ masses $\sim 1$ TeV, these ratios were shown to be useful for coupling determinations but suffered from small statistics. We note in Fig. 12, however, that $r_{\nu W}$ (and similarly $r_{\nu Z}$) grow like $\sim \log^2(M_{Z'}/M_W)$ due to the near infrared and co-linear singularities in the relevant graphs. This renders them potentially far more useful than at lower collision energies although clearly $r_{\nu W}$ should be the focus of our attention. For example, for a $Z'$ mass of 15 TeV in the LRM the cross section for the $l^\pm \nu W^\mp$ final state is $\sim 50$ ab. One difficulty at these energies is the rather large boost of the final state $W, Z$ and its small opening angle with respect to the lepton from which it was emitted, i.e., isolation issues. Further, if the $W, Z$ are found through their dijet decay modes these two jets will not allow for $W, Z$ separation and will also likely appear as a single jet. This final state warrants further study at the FHC.

As a final potential probe of $Z'$ couplings, we can consider the cross sections for the associated production of the $Z'$, observed via its leptonic decay mode as usual, together with some other SM gauge field, a high-$p_T \gamma$, $W$ or $Z$ [4] produced via ‘initial state radiation’. Scaling these cross sections to that for ordinary $Z' \rightarrow l^+ l^-$ production yields a set of observables, $R_V(=\gamma, W, Z)$, that are immune to the possible existence of non-SM decay modes. Fig. 13 shows both the production cross sections for these final states as well as the associated ratios $R_V$ assuming a 10 TeV $Z'$ mass at the 100 TeV FHC. Note that in the $V = \gamma$ case, a $p_T$ cut of 100 GeV has been applied to the final state photon. (The above comments about the $W$ and $Z$ final state identification in dijets will also apply here as well.) These results show that the associated production observables will suffer from somewhat low statistics if only $\sim 1$ ab$^{-1}$ of integrated luminosity is available at the FHC but they still warrant further study at the FHC.

3 New $W'$ Bosons

We now turn our attention to new $W'$ gauge bosons which are generally far less well studied than are the $Z'$. As in the $Z'$ case the first issue to address is the $W'$ production cross section at the 100 TeV FHC; as for the $Z'$ we limit ourselves to final states involving lepton tags so that the primary discovery channel is $W' \rightarrow l \nu$ with the $\nu$ appearing as a large amount of MET. All calculations for the $W'$ will be performed in the same manner as in the $Z'$ case above making use of the same inputs and assumptions.

Here we face an immediate issue: in essentially every model in the literature the couplings of the $W'$ to SM fermions are either purely LH or RH. Assuming that neutrinos are Dirac fermions so that this final state occurs in both cases and that, apart from phases, the RH and LH CKM mixing matrices are the same (which is a likely occurrence in, e.g., the LRM) then in the NWA limit the $W'$ production cross section is independent of this helicity choice [18]. The resulting cross section is shown in Fig. 14 for both $\sqrt{s} = \text{80}$ and $\text{100}$ TeV for comparison purposes. Here we can observe several things (that will be seen in more detail below): (i) At $\sqrt{s} = \text{80(100)}$ GeV the discovery reach is $\sim 20.6(31.6)$ TeV while (ii) the 95% CL exclusion limit is found to be 26.6(35.5) TeV. (iii) At 100 TeV, if exotic modes are present to reduce the $W'$ leptonic branching fraction by a factor of 2, then the corresponding discovery reach

Figure 13: (Top) Associated $VZ'$ production cross section followed by $Z' \rightarrow l^+l^-$ for $V = W^\pm$ (blue), $V = Z$ (green) and $V = \gamma$ with $p_T > 100$ GeV in the $E_6$ scenario taking a $Z'$ mass of 10 TeV. (Bottom) The corresponding ratios $R_V$. 
is reduced by $\simeq 2.2$ TeV. It is important to remember that since the $W'$ couplings are either LH or RH, determining which of these is realized is the primary goal after the $W'$ discovery.

Figure 14: $W'^\pm \rightarrow l^\pm \nu$ production cross section in the NWA as a function of the $W'$ mass at both $\sqrt{s} = 80, 100$ TeV.

Of course the actual way that a $W'$ would be discovered would be via the observation of an excess in the number of events at the high end of the transverse mass ($M_T$) distribution formed from the charged lepton and the MET as in the case of the SM $W$. (Here we will need to assume that the FHC detector(s) can easily identify large amounts of MET with ATLAS-like resolution.) To this end it is instructive to examine these distributions for different values of the $W'$ mass assuming either LH or RH couplings to the usual SM fermions. The results for $W'$ masses of 12, 15, 20 and 25 TeV are shown in Figs. 15 and 16 on log and linear scales respectively. Several things are immediately apparent: (i) the $W'$ for all these masses, whether LH or RH, is clearly visible above the SM background in a statistically significant way. (ii) The behavior of the $M_T$ distribution in the neighborhood of the Jacobian peak is the same (within statistics) whether the $W'$ is LH or RH. This

---

Here we display both log and linear scale event rate plots as we can learn something from both of these projections.
conforms with our expectations from the NWA analysis above. (iii) The overall shapes of the $M_T$ distributions for the LH and RH $W'$ couplings are not the same. This is particularly noticeable in two regions: for $M_T \sim 0.4 M_{W'}$ and above the Jacobian peak. In the lower mass region we see that the LH result lies below the RH one whereas above the Jacobian peak the reverse is true. This difference is due to the interference (or lack thereof) between the $W'$ and the SM $W$ amplitudes. In the LH case, these amplitudes have opposite signs below the Jacobian peak but add constructively above it. In the RH $W'$ case, however, there is no interference with the SM $W$ amplitude since the SM fermions in both the initial and final states are treated as massless. It is clear from these Figures that this difference in the $M_T$ distributions is certainly visible (at this assumed integrated luminosity) for $W'$ masses as large as 20 TeV and may be potentially so even in the 25 TeV mass case although this is still $\simeq 6.5$ TeV below the corresponding discovery reach. Clearly no difference would be observable for a mass of 30 TeV although an excess of events would still be seen in both cases.

Although the shape of the $M_T$ distribution is a powerful probe of the handedness ($h_{W'} = 1(-1)$ for LH(RH) couplings) of the $W'$, it would very useful to have other observables available to also determine this quantity. In the $Z'$ discussion above we saw that $A_{FB}$ was a useful tool to get at the corresponding couplings. Here, since the SM fermions couple to the $W'$ as $\bar{f} \gamma \mu (1 - h_{W'} \gamma_5) f' W^\mu$, the corresponding asymmetry on the $W'$ pole in the NWA would behave as

$$A_{FB} \sim \frac{h_{W'}^2}{(1 + h_{W'}^2)^2},$$

which trivially gives the same result for both helicities and is thus useless for present purposes. Again, as in the $Z'$ case, one might attempt to measure the polarization of the $\tau$ in $W' \rightarrow \tau \nu_\tau$ but it is likely to be even more difficult in this case due to the additional MET and busy detector environment. Building further on our $Z'$ experience we could try to examine both the associated $W'W$ production process (which would likely have $Z$ contamination if $W \rightarrow jj$ is used) or the rare bremsstrahlung-like decay $W' \rightarrow l^+ l^- W$ (here cutting away the $Z$ pole region) for helicity sensitivity. Naively, if the $W'$ were purely RH both these processes would be absent at tree-level so that just their simple observation would inform us that the $W'$ is LH. However, since a traditional $W'$ only arises from an additional $SU(2)$ group factor, it is always accompanied by a $Z'$ due to gauge invariance so that vertices such as $W'ZW$ and/or $W'ZW$ might be present which will not necessarily turn on or off depending upon the helicity of the $W'$ coupling to the SM fermions. Thus some care would be required in interpreting the observation of either of these processes and they both warrant further investigation.

Since these NWA-like processes do not appear to be very promising, we turn to a number of asymmetry distributions that one can form using the $l +$MET discovery mode of the $W'$. Since we already know about the possible $W - W'$ interference as a probe of the coupling helicities it is worthwhile to take advantage of this. Although we’ve shown that $A_{FB}$ near

---

7However, as discussed in detail in Ref. [18], there are no known models with a RH $W'$ where these potentially dangerous vertices are not suppressed by gauge boson mixing angles.
Figure 15: Transverse mass distributions for $W'$ production at $\sqrt{s} = 100$ TeV as discussed in the text. The SM background is shown in yellow whereas the signal for a LH(RH) coupled $W'$ is shown in red(blue). The upper left(right) panel is for a $W'$ mass of 12(15) TeV whereas the lower left(right) panel corresponds to a mass of 20(25) TeV. An integrated luminosity of 1 ab$^{-1}$ has been assumed in obtaining these results.
Figure 16: Same as in the previous Figure but now showing with a linear vertical scale.
the Jacobian peak region is insensitive to this helicity choice we might wonder if we can learn something by examining lower $M_T$ values where this interference is certainly most relevant. The asymmetry predictions for $W'\pm$ and for $W'-$ are found to be slightly different (due to the pdfs) but here we combine them, weighted by their associated cross sections, to increase statistical sensitivity while still integrating over the rapidity. As in the $Z'$ case we impose a minimum rapidity cut here in an attempt to define the initial quark direction so that the angle $\theta^*$ can be determined. We assume, as we did in the $Z'$ case, that a mis-identification of this angle can be corrected for statistically using Monte Carlo. The top panel of Fig. 17 show the results of this calculation for $A_{FB}(M_T)$ employing 5 ab$^{-1}$ and a relatively light $W'$ of mass 12 TeV. Clearly there seems to be very little power here to resolve the LH vs. RH dichotomy with this level of statistics. Alternatively we can focus on the expected interference region, here taking $M_T$ in the 3-9 TeV range and examine the rapidity dependence of the $A_{FB}$ distribution of the $W'$ itself. Since this distribution is odd in $y_{W'}$ we fold it over to increase statistics. We also can again combine the results for $W'^+$ and $W'^-$ by a sign flip and event weighting to increase the statistics even further. Unfortunately, as the lower panel of Fig. 17 shows, this observable assuming even this large value of the integrated luminosity cannot distinguish between the two helicity possibilities even for a relatively light $W'$ of mass 12 TeV.

There still remains other asymmetries which we can form with this same final state: we first consider is the charge asymmetry, $A_{WQ}(y_W)$:

$$A_{WQ}(y_W) = \frac{N_+(y_W) - N_-(y_W)}{N_+(y_W) + N_-(y_W)},$$

where $N_{\pm}(y_W)$ are the number of events with charged leptons of sign $\pm$ in a given rapidity bin. Note that at pp colliders, $A_{WQ}(y_W)$ is symmetric under $y_W \rightarrow -y_W$ so that we can again fold the distribution around $y_W = 0$ to increase statistics. The upper panel in Fig. 18 shows this distribution, integrated over the interference region $3 \leq M_T \leq 9$ TeV, assuming $M_{W'} = 12$ TeV and assuming a luminosity of 5 ab$^{-1}$. It is clear that at this level of statistics the two distributions are reasonably indistinguishable. As a final asymmetry possibility, we consider is the rapidity asymmetry for the final state charged leptons themselves, $A_{\ell}(y_{\ell})$:

$$A_{\ell}(y_{\ell}) = \frac{N_+(y_{\ell}) - N_-(y_{\ell})}{N_+(y_{\ell}) + N_-(y_{\ell})},$$

which is an even function of $y_{\ell}$ so that this asymmetry too can be folded around $y_{\ell} = 0$. The resulting distribution can be seen in the lower panel of Fig. 18 for the same $W'$ mass and integrated luminosity. Here we again see hardly any model differentiation between the two helicity choices.

From this general discussion of possibly asymmetries that one can form employing this leptonic final state we can conclude that their overall usefulness in coupling helicity determination will require very high integrated luminosities beyond the 5 ab$^{-1}$ employed in this survey unless the $W'$ is significantly lighter than our 12 TeV test example (by at least a few TeV). Clearly the shape of the $M_T$ distribution appears to be the lone observable employing ‘modest’ statistics that will be available to determine the $W'$ coupling helicity.
Figure 17: (Top) Rapidity integrated values of $A_{FB}$ for the sum of $W'^+$ and $W'^-$ production as a function of the transverse mass assuming a $W'$ mass of 12 TeV and a luminosity of 5 ab$^{-1}$. Here the LH(RH) helicity result is shown in red(blue). (Bottom) $A_{FB}(y_W)$ for $y_W \geq 0$ and integrated over the range $3 \leq M_T \leq 9$ TeV for a $W'$ mass of 12 TeV and a luminosity of 5 ab$^{-1}$. The red(blue) points are for the LH(RH) $W'$ coupling.
Figure 18: (Top) The charge asymmetry as a function of the $W'$ rapidity, $A_{WQ}(y_W)$, integrated over the range $3 \leq M_T \leq 9$ TeV for a $W'$ mass of 12 TeV and a luminosity of 5 ab$^{-1}$. The red (blue) points are for the LH (RH) $W'$ coupling. (Bottom) The lepton asymmetry, $A_\ell(y_\ell)$ as a function of the lepton rapidity for the same physical situation and color labeling.
4 Conclusions

$Z'$ and $W'$ production are standard benchmarks for study of the physics capabilities of any new collider. In this paper, we have examined the production properties of these new particles at the FHC, in particular, with eye towards understanding its ability to explore their couplings to the usual SM fermions. This is a necessary first step in uncovering the underlying theory from which such new particles might spring. Of course the FHC is a long way from where we are now and one needs to make extrapolations on the theoretical side (e.g., pdfs, etc) as well as make some guesses as to what objects might be well measured on the experimental side at such energies. For example, final states composed of purely hadronic objects or observables requiring b-tagging might be generally difficult to employ given the expected number of multiple interactions at 100 TeV with reasonable luminosities. Furthermore, it is likely that muon momenta in the multi-TeV range would be difficult to measure with high precision without enormous magnetic fields and/or bending radii. Here, we have assumed that electron energies (and to some extent MET for the $W'$ case) can be as well measured by the FHC experiments as is presently done by the LHC experiments. Given these caveats, it is quite clear that the FHC will not only provide a huge step in the reach for these $Z'$ and $W'$ states but will allow for a sufficient number of electron-based observables to be examined so that we can learn something substantial about their couplings to the SM. If multiple interactions could be dealt with and muon-based observables can also be employed, these conclusions will only be strengthened. It is not likely, however, that such information would be obtainable for new gauge boson masses which lie within $\sim 5 - 10$ TeV of the corresponding discovery reaches without significant luminosity increases after the fact (due to simple statistical limitations) or through the application of observables we have not considered here. In performing these studies we have employed a very familiar and long-used set of models with which we can make direct comparisons to other previous experimental and theoretical analyses. However, it is important to recall that this set, though somewhat representative of a more general class of theories, does not in any way span the full range of possibilities that experimenters might encounter at the FHC. Further study of new gauge boson physics at the FHC is certainly needed.

Clearly, much work will be required to understand what the full capabilities of the FHC might be. However, it is clear that the FHC would provide a giant step forward in the search for BSM physics and hopefully its construction will be realized sometime in the future.

Appendix

It is sometimes useful to ask what would happen to the discovery reach for $Z'$ and $W'$ gauge bosons if their couplings differed from those in specified in a given model, particularly if they were weaker. To attempt to address this question here, we briefly consider the SSM $Z'/W'$ gauge bosons but with couplings that differ in overall strengths than those discussed above. Extrapolation to larger couplings is rather straightforward as in the mass ranges of interest the signals remain in a region where there is essentially no (non-fake) SM backgrounds. This is of course no longer true when we consider weaker couplings and correspondingly smaller masses. In particular, once a region of low mass with significant SM background is reached one quickly becomes dominated by the systematic errors associated with our knowledge of this background due to the large integrated luminosities that we consider. This is certainly a subject worthy of some detailed study by the future FHC experimental collaborations as this relies on more of the detailed properties of possible detectors than is within the scope of the present work. If we assume that these backgrounds can be controlled and understood at the same $\sim 25\%$ level of uncertainty as claimed by ATLAS and CMS for the HL-LHC [12], then we can get an estimate of what the discovery reach might be for these $Z'/W'$ states with weaker couplings. To get an idea of what might be possible at the FHC we will make this assumption below for the dilepton invariant mass region above a few TeV.

Following this approach we obtain the results as shown in Fig. 19 for both the SSM $Z'$ and $W'$ with scaled couplings. In the $Z'$ case, we see that for $g/g_{SM} = 0.1(0.05)$ the discovery reach for $1 \text{ ab}^{-1}$ is reduced to $\sim 11(8)$ TeV. In the corresponding $W'$ case we see that the discovery reach is reduced to $\sim 17(13)$ TeV. In both cases we note that at very low masses and small relative couplings the search reaches ‘saturate’ in the sense that smaller couplings cannot be probed with this level of systematic error given our rather simplified approach. This happens for masses below $\sim 5$ TeV, with corresponding couplings less than $g/g_{SM} = 0.025$, in the case of the $W'$ and at masses of $\sim 4$ TeV and the corresponding coupling below $g/g_{SM} = 0.02$ for the $Z'$. We emphasize to the reader that these results are only approximate but do give us some indication of what might be achievable at the FHC.
