Abstract

BACKGROUND
Cancer survivors have a higher risk of developing secondary cancer, with previous studies showing heterogeneous effects of prior cancer on cancer survivors.

AIM
To describe the features and clinical significance of a prior malignancy in patients with gastric cancer (GC).

METHODS
We identified eligible patients from the Surveillance, Epidemiology, and End Results (SEER) database, and compared the clinical features of GC patients with/without prior cancer. Kaplan-Meier curves and Cox analyses were used to assess the prognostic impact of prior cancer on overall survival (OS) and cancer-specific survival (CSS) outcomes. We also validated our results in The Cancer Genome Atlas (TCGA) cohort and compared mutation patterns.

RESULTS
In the SEER dataset, of the 35492 patients newly diagnosed with GC between 2004 and 2011, 4,001 (11.3%) had at least one prior cancer, including 576 (1.62%) patients with multiple cancers. Patients with a prior cancer history tended to be elderly, with a more localized stage and less positive lymph nodes. The prostate (32%) was the most common initial cancer site. The median interval from initial cancer diagnosis to secondary GC was 68 mo. By using multivariable Cox analyses, we found that a prior cancer history was not significantly associated with OS (hazard ratio [HR]: 1.01, 95% confidence interval [CI]: 0.97–1.05).
INTRODUCTION

With the successful eradication of *Helicobacter pylori* and healthier lifestyles, gastric cancer (GC) incidence and mortality have steadily declined in the United States[1,2]. In recent decades, thanks to active cancer screening and effective therapies, many cancer survivors now enjoy relatively longer lives. Although risk factors for primary GC incidence and prognosis are well documented[2,3], little is known about secondary GC occurrence in cancer survivors.

With the increasing aging populations, it is anticipated that the prevalence of secondary cancer in cancer survivors will increase[4]. A recent study revealed that approximately 17.8% of elderly (≥65 years) and 7.3% of young adults (<65 years) with newly diagnosed GC have a prior cancer history[5].

Due to inadequate selection criteria, patients with prior cancers are routinely excluded from oncology clinical trials[5,6]; thus, a substantial number of patients may have lost access to cutting-edge therapies and care. The impact of prior cancer on a current malignancy is often inconsistent and varies by cancer type (e.g., pancreatic, prostate, esophageal, Non-Hodgkin’s lymphoma, gastrointestinal, and lung cancers)[7-16]. To the best of our knowledge, there is a dearth of data on the characteristics and survival outcomes of GC patients with prior cancer. Similarly, there is a lack of real-world evidence to address these issues.

In this study, we characterized GC patients with a prior cancer history and estimated survival outcomes from real-world data. Understanding the prognostic impact of prior cancer on GC patients may have significant implications for improved therapeutic strategies and surveillance.

MATERIALS AND METHODS

Data sources and populations

We identified eligible patients with newly diagnosed and histopathologically proven GC between 2004 and 2011 in 18 Surveillance, Epidemiology, and End Results (SEER) registries (https://seer.cancer.gov/), which covered approximately 30% of the United States population[17]. We included patients aged ≥18 with active follow-up to the end of 2014. Tumor 83 site codes (C16.0, C16.1, C16.2, C16.3, C16.4, C16.5, C16.6, C16.8, and...
C16.9) were used for GC identification according to the International Classification of Diseases for Oncology 3rd edition. A sequence number was used to identify the number of multiple primaries. A sequence number = 0 indicated that an individual had only one primary cancer, and a larger number indicated more than one primary cancer. To reduce the possibility of misclassifying synchronous metastases, a latency period of at least 6 mo was required from initial prior cancer diagnosis to secondary GC. For initial prior cancer, we excluded cases termed as GC. We categorized prior malignancies of interest including prostate, gastrointestinal, hematologic, breast, genitourinary, and lung cancers.

The following information was collected from the SEER database: age, sex, race, marital status, tumor sites for the prior malignancy and GC, lymph nodes examined, positive lymph nodes, SEER stage, GC grade, and current and prior cancer therapies. To validate the impact of prior cancer on GC patient survival, we used The Cancer Genome Atlas (TCGA) database as an external validation source. Primary gastric adenocarcinoma in TCGA with or without prior malignancy was included. Clinicopathological and genomic data were also queried in TCGA database.

Statistical analyses
Baseline characteristics from GC patients with or without prior cancer were summarized and investigated using the $\chi^2$ test. For patients with prior cancer, site distribution, stages, and main therapies were classified. To investigate the impact of a prior cancer, we calculated overall GC survival and cancer-specific 3-year survival rates with and without prior cancer, stratified by age. Kaplan-Meier curves were constructed for patients with and without prior cancer, and survival differences were examined using the log-rank test. Furthermore, to validate our results, we adopted a multivariate Cox proportional hazards model to estimate hazard ratios (HRs). Using the maftools package in R, the frequency and visualization of gene mutations in TCGA was performed. Differentially expressed genes (DEGs) in TCGA samples, with and without prior malignancy, were analyzed using the Limma package. DEGs were considered genes where fold change > 2 and $P < 0.05$. All $P$ values were two-sided and statistical significance was accepted at $P < 0.05$. All statistical analyses were performed using STATA version 13.0 (StataCorp, College Station, TX, United States) and R software version 3.40 (www.r-project.org).

RESULTS

Demographic and clinicopathological characteristics
In the SEER dataset, from 2004 to 2011, 35492 patients were identified with newly diagnosed GC, of which, 4,001 (11.27%) had one or more prior malignancy, including 576 (1.62%) patients with multiple malignancies. Baseline patient demographic and clinicopathological characteristics are described in Table 1. When compared with patients with primary GC only, those with a history of prior cancer were more likely to be elderly, male, white, and married. The proportion of cancers arising at cardia and fundus sites, with negative lymph nodes, at a localized stage, and with well/moderate differentiation, were higher in patients with prior cancer. In terms of GC therapeutic options, no significant differences were observed in the percentage of surgeries. In patients without prior cancer, radiotherapy and chemotherapy were more common. From TCGA dataset, 13 patients had one or more prior malignancy and 376 patients had no prior malignancy.

Regarding initial cancer sites, the prostate (32%) was the most common site, followed by gastrointestinal tract (17%), genitourinary (15%), breast (14%), others (10%), hematological system (7%), and the lung (5%) (Figure 1A). Unsurprisingly, the majority of prior cancers were either at localized (37%) or localized/regional stages (28%), with only 5% at distant stages (Figure 1B). Regarding therapeutic options for initial cancers, surgery was the most common modality, with most cases receiving multiple therapies (Figure 1C). The median time of initial malignancy to the time of subsequent GC diagnosis varied across initial cancer sites (from 50-78 mo, average = 68 mo; Supplementary Table 1). For breast and genitourinary cancer survivors, this interval exceeded 68 mo, whereas it was only 50 mo for lung cancer survivors.

Effects of prior cancer on GC patient survival in the SEER dataset
Among the primary GC patients in the SEER dataset, 25,592 (81%) died and 22,223 (87%) GC-related deaths were recorded during follow-up. In GC patients with prior cancer, 3407 (85.28%) died, including 544 initial cancer-related deaths and 2,353 GC-
Table 1 Baseline characteristics of patients diagnosed with gastric cancer (n = 35,492) by prior cancer status

Figure 1 Distribution of initial site (A), stage (B) and therapeutic options (C) of prior cancers in gastric cancer patients with a history of cancer. The all-cause and GC-specific 3-year survival rates of primary GC patients were 26.42% (95% confidence interval [CI]: 25.90%–26.94%) and 30.91% (95% CI: 30.34%–31.47%), respectively, while for patients with a history of prior cancer, theses rates were 25.20% (95% CI: 23.80%–26.63%) and 38.03 (95% CI: 36.27%–39.79%), respectively (Table 2, Supplementary Table 3). Thus, it appeared that patients with prior cancer had a higher GC-related survival rate. Considering age may have had a role, we calculated the survival rates stratified by age. In either young or elderly patients, a higher GC-specific survival rate was observed in those with prior cancer. In terms of different initial cancer sites, lung cancer survivors had lower all-cause and cancer-specific survival (CSS) rates than those with other initial cancer sites. From Kaplan-Meier curves, patients with prior cancer had a significantly worse overall-survival (OS) and better GC-specific survival rate (log-rank tests both $P < 0.05$) (Figure 2). We also constructed multivariable Cox regression models to confirm the effects of prior cancer on survival outcomes. A related deaths (Supplementary Table 2).
Table 2 Overall 3-year survival rate of gastric patients stratified by age

| Prior initial cancer site | All-cause survival (95%CI) | Overall | Age < 65 yr (%) | Age ≥ 65 yr (%) |
|---------------------------|---------------------------|---------|----------------|----------------|
| No prior cancer           | 26.42 (25.90, 26.94)       | 28.95 (28.14, 29.77) | 24.49 (23.82, 25.16) |
| With prior cancer         | 25.20 (23.80, 26.63)       | 30.12 (26.68, 33.62) | 24.08 (22.55, 25.65) |
| Prostate                  | 24.79 (21.39, 28.32)       | 25.33 (16.23, 31.21) | 25.16 (21.35, 29.14) |

Figure 2 Kaplan–Meier survival curves of gastric cancer patients with and without a history of prior cancer. A: All-cause survival; B: Gastric cancer-specific cancer survival.

Effects of prior cancer on GC patient survival in TCGA

We observed that 329 patients (329/376, 87.5%) without prior cancer had molecular alterations; the top mutated genes were titin (TTN), tumor protein 53 (TP53), mucin 16 (MUC16), AT-rich interactive domain-containing protein 1A, and lipoprotein receptor-related protein 1B (LRP1B) (Figure 3A). Ten patients (10/13, 76.92%) with prior cancer had molecular alterations; the top mutation genes were MUC16, TP53, TTN, contactin associated protein 2, and LRP1B (Figure 3B). We observed no significant differences in

Somatic mutations between GC patients with or without prior cancer (Figure 3C). Distinct to the SEER dataset, TCGA appeared to show a survival benefit toward patients with prior cancer. Due to insufficient sample numbers, we observed no significant OS between GC patients with or without prior cancer (Figure 3D). Also, we identified 42 DEGs between cancer groups, with 15 upregulated and 27 downregulated genes identified in the prior cancer group. Additionally, we constructed a volcano map (Figure 3E) to show the distribution of these 42 DEGs.

DISCUSSION

Cancer survivors are at higher risk of developing secondary malignancies\[18,19\]. With increasing numbers of cancer survivors having complicated dual or even multiple malignancies, the prognostic impact of previous cancer on cancer survival remains controversial. A pan-cancer study investigated the distinct effects of prior cancer across 20 cancer types\[20\]. For colorectal, sarcoma, melanoma, breast, cervical, endometrial, prostate, urothelial, orbital, and thyroid cancers, a prior cancer history contributed to a poor OS, while nasopharynx, gastrointestinal tract, lung, ovary, and brain cancer patients, with prior cancer, had a similar OS to patients without prior cancer\[20\]. In our population-based study, more than 10% of patients with newly diagnosed GC had a prior cancer history, similar to that reported by Murphy et al\[5\]. Newly diagnosed GC patients with prior cancer were older, suggesting that age is an independent risk factor for secondary malignancies\[21\]. The proportion of localized stages and negative lymph nodes were higher in patients with a prior cancer history, suggesting that cancer survivors may receive more active surveillance and that their cancer may be incidentally diagnosed at earlier stages\[22,23\]. Unsurprisingly, prostate cancer was the most common prior tumor type, suggesting an indolent clinical course. Similar results were identified for lung cancer patients\[24\]. The interval between initial malignancy and GC suggested the GC risk increased after five years of prior cancer diagnoses.

In oncology clinical trials, a substantial proportion of cancer survivors are excluded due to stringent eligibility criteria, and the assumption that these patients have inferior survival\[6,24-27\]. A previous study reported that the heterogeneous impact of a prior cancer history should be reconsidered according to the specific cancer type\[20\]. Thus, it is inappropriate to assume a prior cancer is a risk factor for mortality in a newly diagnosed cancer. In our study, using the SEER database, GC patients with a prior cancer history had similar 3-year survival rates compared to those without a prior cancer history. Despite a survival benefit trend, these data were not significant for patients with prior cancer.

A similar result was identified and validated in TCGA cohort, and suggested that a prior cancer history did not adversely affect the overall prognosis in GC patients. Regarding CSS, patients with prior cancer had superior GC-specific survival after particular variables were adjusted. It is unclear why a prior cancer history could improve GC-specific survival. Cancer survivors may undergo active cancer surveillance, thereby having an early cancer stage and improved survival, which may cause length bias and lead-time bias\[28-30\]. As gene mutations underlie most cancers, we hypothesized that patients with prior cancers harbored more molecular mutations, however, no significant mutation counts were associated with prior cancer status in the TCGA cohort.

genes in patients without prior cancer patients with prior cancer; C: Distribution of somatic mutation counts between patients with and without prior cancer; D: Kaplan–Meier survival curves of overall survival in patients with and without prior cancer; E: Volcano plot of differentially expressed genes between patients with and without prior cancer.

In our study, we could not avoid bias as the percentage of early stage GC was more frequent in patients with prior cancer. However, we did not believe this bias was responsible for GC-specific survival advantages because a prior cancer was also associated with better GC-specific survival in the localized stages (HR = 0.82, 95%CI: 0.74–0.91). We speculated that higher competing mortality risks (either due to prior cancer or other factors) in patients with prior cancer may have accounted for GC-specific survival benefits[31]. Further studies are required to address these observations.

In subgroup analyses, age did not affect the impact of a prior cancer diagnosis. A prior cancer had no significant influence on OS, but improved CSS in GC patients. We also noted that the prognostic impact of a prior cancer was independent of the time of previous cancer diagnosis, suggesting that GC patients with a prior cancer diagnosis could be considered for trial enrollment regardless of the time.

We observed that the impact of a prior cancer history on survival was varied across different cancer types. In 2009, Pulte et al[10] reported that non-Hodgkin’s lymphoma patients with prior malignancies had worse prognoses than those without prior cancer. Youn et al[32] subsequently showed a reduced survival time for Hodgkin’s lymphoma survivors with secondary gastrointestinal cancer. In contrast, opposite trends were identified in other studies: Smyth et al[11] showed that gastrointestinal cancer patients with/without prior cancer had comparable OS and gastrointestinal cancer-specific survival times. Also, in early or advanced lung cancer stages, no differences in OS were noted between patients with and without prior cancer[24,33]. Pruitt et al[24] demonstrated improved lung CSS outcomes in patients with prior cancer. For stage IV esophageal cancer, a prior malignancy had no impact on OS[9]. A recent study explored the prognostic effect landscape across 20 prior cancer types[20]. However, this study primarily focused on pan-cancer and did not characterize specific clinical features and the specific impact of GC with a prior cancer history. Thus, our study filled this knowledge gap.

Our study had several limitations. The SEER database did not provide detailed chemotherapy and radiation information, and the efficacy and tolerability of prior therapies were unclear. Other covariates, such as Helicobacter pylori infection status, genetic information, and comorbidities were unavailable. Also, we could not completely exclude the possibility of GC metastatic misclassifications from earlier tumors. Finally, our findings were based on the SEER database and TCGA cohorts, thereby limiting overall generalizability to other populations. Further studies or independent cohorts are required to validate our findings and conclusions.
CONCLUSION

In the SEER database, 11.3% of newly diagnosed GC patients had a prior cancer history, with GC occurring within 6 years after prior cancer diagnosis. GC patients with a prior cancer history had a non-inferior OS, and the CSS was slightly improved. We suggest that in future clinical trials, broader inclusion criteria for GC patients with previous cancer should be considered in order to obtain the best inclusion rate and generalizable results.

ARTICLE HIGHLIGHTS

Research background
Cancer survivors had a higher risk of developing secondary cancer, and previous studies have indicated the heterogeneous effects of prior cancer on cancer survivors.

Research motivation
To evaluate prior malignancy on patients with gastric cancer (GC).

Research objectives
To describe the features and clinical significance of a prior malignancy on patients with GC.

Research methods
We identified eligible cases from the Surveillance, Epidemiology, and End Results (SEER) database and compared clinical features of GC patients with/without prior cancer. We adopted Kaplan-Meier curves and Cox analyses to assess the prognostic impact of a prior cancer on the overall survival (OS) and GC-specific survival outcomes. We also validated these results in The Cancer Genome Atlas (TCGA) cohort and compared mutation patterns.

Research results
In the SEER dataset, 35,492 patients newly diagnosed with GC during 2004-2011, 4,001 (11.3%) cases had at least one prior cancer, including 576 (1.62%) cases with multiple prior cancers. Patients with a history of prior cancer tended to be elderly, with a more localized stage and less positive lymph nodes. Prostate (32%) was the most common initial cancer site. The median interval from the initial diagnosis of malignancy to secondary gastric cancer was 68 mo. A history of prior cancer was not significantly associated with overall (hazard ratio:1.01, 95% confidence interval: 0.97-1.05) survival in multivariable Cox analyses.

Research conclusions
The prognosis for GC patients with a diagnosis of prior cancer was not inferior to primary GC patients.

Research perspectives
The prognosis for GC patients with a diagnosis of prior cancer was not inferior to primary GC patients. Our results suggest that a wide range of conclusions should be considered in the clinical trials of GC patients with a previous cancer to obtain the best inclusion rate and generalizable results.
