KEYWORDS
Dkk1; osteoblasts; periodontitis; Wnt3a

Abstract  Background/purpose: Periodontitis is an inflammatory, destructive disease caused by periodontal bacteria, and its molecular mechanism remains unclear. The aims of this study are to evaluate the expressions of Wnt3a and Dkk1 in experimental periodontitis (EP) and preliminarily explore their roles in periodontal diseases.

Materials and methods: A total of 64 six-week-old male Sprague–Dawley rats were randomly divided into a normal group and an EP group. The EP group was prepared by using silk ligature combined with intraoral bacteria inoculation. To assess the periodontal inflammation and bone destruction extent, hematoxylin and eosin staining and tartrate-resistant acid phosphatase staining was performed 2 weeks, 4 weeks, and 6 weeks after the modeling, respectively, and immunohistochemistry and enzyme-linked immunosorbent assay were also performed to detect the changes of Wnt3a and Dkk1 in periodontal tissue and plasma.

Results: Wnt3a expression was significantly decreased in the EP group when compared with the normal group (P < 0.05). Meanwhile, Dkk1 expression was significantly increased in the EP group when compared with the normal group (P < 0.05).

Conclusion: The expression of Wnt3a and Dkk1 was well correlated with EP. It is suggested that Wnt3a and Dkk1 may be involved in periodontal diseases.

Introduction

Periodontitis is a type of inflammatory, destructive disease caused by periodontal bacteria, and its molecular mechanism is unclear. Studies had shown that the major pathogen causing periodontitis is Porphyromonas gingivalis. The proinflammatory cytokines are produced by the host cells such as leukocytes and other cells after the challenge of bacteria, and then promote the release of chemokines and prostaglandin so as to cause bone damage; meanwhile, such proinflammatory cytokines could inhibit the proliferation signals, such as mitogen-activated protein kinase and c-Jun N-terminal kinase, thus resulting in proproliferation signals, such as mitogen-activated protein.

While, such proinflammatory cytokines could inhibit the proliferation signals, such as mitogen-activated protein kinase and c-Jun N-terminal kinase, thus resulting in the growth inhibition of normal cells followed by bone destruction.

The Wnt signal is an important signaling pathway that extensively exists in invertebrates and vertebrates and could promote cell proliferation. Its key factor, Wnt3a, could bind LRP5 and β-catenin so as to form complexes and participate in a series of life processes such as embryonic development, organogenesis, and tumorigenesis. Studies had shown that Wnt3a has important regulatory roles in development, organogenesis, and tumorigenesis.

Periodontitis 221

Establishment of animal periodontitis model

A total of 64 male Sprague–Dawley rats, aged 6–8 weeks (220–240 g), were randomly divided into two groups: the normal group (group N, n = 32) and the periodontitis group (group P, n = 32); the rat EP model was prepared according to Huang et al 12 and Branco-de-Almeida et al.13 After we ligatured the neck of the maxillary second molar tooth with silk, each rat was orally administered ampicillin (20 mg/d) with water so as to inhibit other bacteria that are nonbeneficial to the growth of P. gingivalis. Three days later, each rat was tube-fed 0.5 mL of 1.5 × 109 CFU/mL P. gingivalis (American Type Culture Collection 33277), and refed once every 48 hours for a total of three times.

After a successful modeling, the animals were sacrificed at 2 weeks, 4 weeks, or 6 weeks, and HE staining, T-ACP staining, immunohistochemistry, and ELISA were performed.

Specimen collection and processing

The blood was sampled from the heart after each rat was killed in the 2nd week, 4th week, or 6th week, followed by centrifugation to obtain the supernatant for the determination of Wnt3a and Dkk1. Each rat was decapitated, and then we rapidly separated the bilateral maxillary alveolar bone, which was then soaked in 4% paraformaldehyde for fixation, followed by dehydration in ethanol series, xylene replacement, and paraffin embedding. Paraffin sections (3 μm thick) were then continuously sliced in turn for the HE staining, T-ACP staining, and immunohistochemical staining of Wnt3a and Dkk1.

Detection of serum factors by ELISA

The changes in Wnt3a and Dkk1 were detected according to the kit instructions, and according to the concentrations and corresponding optical density (OD) values of the standards. The linear regression equation of the standard curve was then calculated so as to calculate the corresponding sample concentrations according to their own OD values.

HE staining

The slices were performed in conventional HE staining, and then the consecutive slices with complete dental crown and root system of adjacent teeth were microscopically observed—particularly, the pathological changes of periodontal tissue between the first and second molars, as well as those between the second and third molars.
T-ACP staining

T-ACP staining was performed according to the kit instructions, and the image analysis system was then used to observe the number of osteoclasts on a third of the alveolar surface of the proximal, middle, and distal crest of the second molar, and the number of osteoclasts within one unit length (1 mm) was then calculated.

Immunohistochemical staining of Wnt3a and Dkk1

The slices were performed using routine immunohistochemical staining, and then we observed the positive expressions of Wnt3a and Dkk1 in the bone cells on the third alveolar crest in the inflammatory area of the second molar. The positive cell was defined to appear as precipitate of brown particles in the bone cell cytoplasm. The slices were placed under a Leica DM4000B high-power (×400) microscope (Hangzhou Top instrument Co, Ltd., Hangzhou, China) to accurately position the target view field. The numerical cell images were then extracted by the imaging system, and then we input the data in the HPIA-1000 high-resolution color pathological image analysis system for the processing. Each specimen was randomly selected from three to five nonoverlapping fields of vision, and we determined the average OD value of the immunopositive particles, and calculated the mean. The expressions of Wnt3a and Dkk1 were then semiquantitatively analyzed.

Statistical analysis

SPSS17.0 statistical package (SPSS Inc., Chicago, IL, USA) was used for the analysis and processing of the experimental data. For the data of each index, we first performed the normality test and the homogeneity of variance test; those that met the normal distribution and homogeneity of variance were then subjected to Least significant difference test (one-way analysis of variance), and paired t test was applied to compare their differences, with \( P < 0.05 \) considered statistically significant.

Ethics statement

This study was approved by the laboratory animal ethics committee of Kunming Medical University.

Results

Changes in serum Wnt3a level

Four weeks after the modeling, the serum Wnt3a level in group P was significantly lower than that in group N; the difference was statistically significant and showed a time-dependent trend. Moreover, in the 6th week of modeling, the serum Wnt3a level was reduced by approximately 67.3% (Table 1).

Changes in serum Dkk1 level

Four weeks after the modeling, the serum Dkk1 level in group P was significantly higher than that in group N; the difference was statistically significant, and showed a time-dependent trend. Moreover, in the 6th week of modeling, the serum Dkk1 level was increased by approximately 57.4% (Table 2).

HE staining

Based on the results of HE staining, group N showed complete alveolar structure, and no alveolar bone destruction was found; only a few inflammatory cells could be seen. Two weeks after the modeling, the alveolar structure was damaged, and the number of inflammatory cells was increased. Four weeks after the modeling, the alveolar structure showed obvious damage; some parts exhibited bone loss, and the number of inflammatory cells was increased significantly. Six weeks after the modeling, the alveolar structure showed severe damage, together with severe bone loss and a large number of inflammatory cells (Figure 1).

Observation of alveolar osteoclasts by T-ACP staining

Two weeks after the modeling, the alveolar osteoclasts level was significantly increased and exhibited statistical significance than that in group N; the alveolar osteoclast level was significantly increased in a time-dependent manner (Table 3, Figure 2).

Changes of Wnt3a in the alveolar crest

Immunohistochemistry showed that the cytoplasm in group N exhibited numerous brown positive cells, but that in...
group P showed a time-dependent decrease, and the difference was statistically significant. In the 6th week of modeling, the number of positive cells was reduced by about 45.6% (Table 4, Figure 3).

### Changes of Dkk1 in the alveolar crest

Immunohistochemistry showed that the cytoplasm in group N exhibited numerous brown positive cells, and that in group P showed a time-dependent increasing trend, and the difference was statistically significant. In the 6th week of modeling, the number of positive cells was increased by about 45.6% (Table 5, Figure 4).

### Discussion

Periodontitis is a class of inflammatory destructive diseases caused by osteoblast-induced osteogenesis reduction and/or osteoclast-induced increase in osteoclasia. During bone remodeling processes, osteoblasts could be migrated to the absorption site, and then secrete bone matrix to form new bones. Furthermore, osteoblasts could regulate the differentiation of osteoclasts via the receptor activator of nuclear factor kappa-B ligand/OPG system, thus affecting the changes of bone mass; therefore, osteoblasts play important roles in the bone remodeling process.

As they perform their functions, osteoblasts would be strictly regulated by multiple signaling pathways, such as the mitogen-activated protein kinase signal, the OPG_receptor activator of nuclear factor kappa-B ligand/OPG system, or the Wnt signal.14,15 The Wnt signaling pathway is a key factor in regulating the embryonic development and self-renewal and differentiation of stem cells, and is considered one of the most important signaling pathways in organisms,

playing significant regulatory roles in all the differentiation aspects of osteoblasts. Studies have found that as endogenous ligands, Wnt7b and Wnt11 regulated the differentiation of osteoblasts, and rats with Wnt5a and Wnt3a knockout showed reduced bone mass; on the contrary, rats with high Dkk1 expression exhibited reduced osteogenesis and bone mass, which might be a result of its impacts toward the end-stage differentiation of osteoblasts. In rats with Dkk1 knockout, osteogenesis was found to be increased, and the formation of osteophyte was also found. Recently, studies have elucidated that the messenger RNA and protein levels of Dkk1 were increased in chronic periodontitis compared to the nonperiodontitis group. The studies cited above showed that the Wnt proteins and the antagonizing factor Dkk1 played important roles in bone remodeling. This study detected the expressions of Wnt3a and Dkk1 by immunohistochemistry and ELISA, and found that Wnt3a was significantly decreased in rats with periodontitis in a time-dependent manner, whereas Dkk1 was significantly increased in a time-dependent manner, indicating that in periodontitis mainly characterized by inflammations, Wnt3a and Dkk1 might play important roles.

The Wnt signaling pathway regulates a variety of biological phenomena such as development, self-renewal of stem cells, metabolism, or cancer in almost all animals. Recent studies have found that the Wnt signaling pathway could regulate the proliferation, differentiation, and osteogenesis of osteoblasts, so it has become the therapeutic target of some bone loss diseases, such as osteoporosis. The Wnt signal could bind its ligands such as LRP5 and Frizzled receptor, and then activate the classic Wnt signaling pathway so as to mediate the ubiquitination of intracytoplasmic proteins, which would then result in the cytoplasmic accumulation and nuclear translocation of b-catenin, and then exert the related biological effects. Moreover, the Wnt pathway could activate the associated transcription factors, such as Runx2 or Msx2, and then promote the osteogenic differentiation of periodontal ligament fibroblasts.

In summary, our study showed that the key factors Wnt3a and Dkk1 were abnormally expressed in EP, so regulating the expressions of the key factors in the Wnt signal might be a promising direction for the treatment of periodontitis. However, many factors in the microenvironment of periodontal diseases would coregulate the occurrence of alveolar bone loss, so further studies are necessary to confirm the specific roles and mechanisms of the Wnt signal in periodontitis.
