(Received 29 February 2016; accepted 13 July 2016; published online 2 August 2016)

We present a universal characterization scheme for chimera states applicable to both numerical and experimental data sets. The scheme is based on two correlation measures that enable a meaningful definition of chimera states as well as their classification into three categories: stationary, turbulent, and breathing. In addition, these categories can be further subdivided according to the time-stationarity of these two measures. We demonstrate that this approach is both consistent with previously recognized chimera states and enables us to classify states as chimeras which have not been categorized as such before. Furthermore, the scheme allows for a qualitative and quantitative comparison of experimental chimeras with chimeras obtained through numerical simulations.

I. INTRODUCTION

Most early studies on chimera states dealt with non-locally coupled phase oscillators, where coherence refers to phase- and frequency-locked oscillators and incoherence to drifting oscillators, respectively.1 Lately, more and more chimera patterns were discovered, where coherence and incoherence is of a different nature. One example is a coupled-map chimera, where the individual elements consist of period-two orbits. There, the coexistence pattern is composed of two synchronous regions corresponding to the two realizations of the period-two orbit, with a spatially incoherent interfacial region, where the spatial arrangement of the two states appear in a random and thus incoherent manner.9 Yet, each state remains a period-2 orbit in time and is thus either synchronized or anti-synchronized to any of the other elements, preserving temporal order. Another example is the so-called amplitude chimera, where the incoherent group is characterized by disorder in the amplitude of the oscillators while all the oscillators in the entire ensemble oscillate with the same frequency.11 Other coherence/incoherence coexistence patterns differ from the classical chimera state by the variability of coherent and incoherent regions, which might both change their sizes and move in space.17,18 Furthermore, the stability properties of these diverse chimera states vary greatly. Many chimeras, among them the original one in systems of nonlocally coupled phase oscillators, are transient for a finite number of oscillators, but have a diverging transient time in the continuum limit $N \to \infty$.19 Others are stable...
already from small ensemble sizes,\textsuperscript{20,21} and still others have finite transient times even in the continuum limit.\textsuperscript{11}

These examples illustrate that the original definition of a chimera state as “a spatio-temporal pattern in which a system of identical oscillators is split into coexisting regions of coherent and incoherent oscillators”\textsuperscript{22} does not cope with recent developments but calls for a more distinct characterization and refinement. There already exist two approaches towards characterization schemes in minimal networks\textsuperscript{20} and for chimeras with non-local coupling,\textsuperscript{23} but they are both restricted to a small class of systems.

In this paper, we propose two measures for characterizing chimera states. Although based on linear methods, these quantities provide what we believe to be a clear and simple definition of chimera states, and, furthermore, they allow for an easy distinction between chimera states with different coherence properties and thus provide a useful classification scheme. In addition, our approach is independent of the coupling scheme and the spatial dimension of the system, and not restricted to phase oscillators, such as the (local) Kuramoto order parameter.\textsuperscript{1}

The paper is structured as follows: In Section II, we introduce a spatial and a temporal correlation measure applicable to arbitrary data sets and define chimera states with the help of these measures. In Section III, these criteria are applied to experimental and simulated data of different chimera states, and in Section IV, a detailed characterization scheme on the basis of the measures is discussed. Details pertaining to the individual systems and to the numerical methods are given in the supplementary material.\textsuperscript{24}

II. CORRELATION MEASURES FOR SPATIAL AND TEMPORAL COHERENCE

A. A measure for correlation in space

For systems with a spatial extent, that is, systems with a local or non-local coupling topology, we employ the local curvature as a measure for the spatial coherence. Hereby, the local curvature of the observable is quantified by the second derivative in one-dimension, or, more generally, by the Laplacian for any number of spatial dimensions. Therefore, we calculate the local curvature at each point in space by re-scaling and applying the discrete Laplacian $D_m$ on each snapshot containing the spatial data $f$. For one snapshot at time $t$ with one spatial dimension, this operation reads

$$\tilde{D} f = \Delta x^2 D f = f(x + \Delta x, t) - 2 f(x, t) + f(x - \Delta x, t),$$

where each data point in $f$ can be either real, complex, or of any higher dimension. In order to clarify this concept, consider the chimera state observed by Kuramoto and Battogtokh in a ring of non-locally coupled phase oscillators.\textsuperscript{1} One realization of the chimera state is depicted in Figure 1(a). Through the application of the discrete Laplace operator, this snapshot is mapped onto a new function as shown in Figure 1(b), with $D_m$ indicating the maximal value of $|\tilde{D}|$. Note that for phase oscillator systems, we apply this operator on the data in the complex plane, that is the phase oscillators are located on a ring with constant amplitude $A$. Then, $D_m$ corresponds to the curvature at an oscillator whose two neighbors are shifted $180^\circ$ in phase, i.e., whose neighboring oscillators are located on opposite positions on the circle. With the re-scaling obtained by multiplying the Laplacian with $\Delta x^2$ in Eq. (1), $D_m$ converges to 4$\pi$ in the continuum limit. In the synchronous regime $\lim_{N \to \infty} |D| = 0$. This means that the synchronous regime is projected onto the $x$-axis through this transformation, while in the incoherent regime $|D|$ is finite and exhibits pronounced fluctuations. Consequently, when we consider the normalized probability density function $g$ of $|D|$, $g(|D| = 0)$ measures the relative size of spatially coherent regions in each temporal realization. For a fully synchronized system $g(|D| = 0) = 1$, while a totally incoherent system gives a value $g(|D| = 0) = 0$. A value between 0 and 1 of $g(|D| = 0)$ indicates coexistence of synchrony and incoherence.

Given this discussion, two important aspects have to be considered. First, the definition of spatial coherence and incoherence is not absolute, but has to be compared to the maximal curvature in each system. Thus, we argue that the characterization of coherence and incoherence is relative and depends on the individual system. Second, even in the coherent regime, there might be some minor change in state (cf. Figure 1(a) above) leading to a non-zero curvature. Hence, we are convinced that in order to characterize something as coherent or incoherent, a threshold value is inevitable, although, as will be shown later, the exact position of the threshold does not change the qualitative outcome.

Considering the two arguments above, we propose that for spatially extended systems, a point for which the absolute local curvature is less than one percent of the maximum curvature present in the system should be characterized as coherent, and as incoherent otherwise.

With the threshold $\delta = 0.01D_m$, our first correlation measure,

$$g_0(t) := \int_0^t g(t, |\tilde{D}|) d|\tilde{D}|,$$

can be used to describe the spatial extent occupied by coherent oscillators, even for systems beyond coupled phase oscillators. An example of $g$ for the Kuramoto model is shown in Figure 2(a). Note that, in general, $g$ is time dependent. Figure 2(b) shows $g_0(t)$ as a function of time. The value of $g_0(t)$ of about 0.3 confirms the interpretation of the state as a
chimera state, while its time-independence reveals that the
degree of coherence is stationary.

For systems without a spatial dimension, i.e., systems with
solely global coupling, curvature is not defined. Nevertheless, we argue that the pairwise Euclidean distances
between the values of all oscillators, \( f_i \),

\[ \mathbf{D} = \{ \bar{D}_{ij} \} = ||f_i - f_j||, \quad i \neq j, \quad (3) \]

are a good measure for synchrony/asynchrony. Again, from
the normalized probability density function \( g \) of \( \mathbf{D} \), a variable,

\[ \tilde{g}_0(t) := \sqrt{\int_0^1 g(t, |\bar{D}|) d|\bar{D}|}, \quad (4) \]

can be obtained that is a measure for the relative amount
of correlated oscillators. Here, the square root arises due to the
fact that by taking all pairwise distances, the probability of
oscillators \( i \) and \( j \) both being in the synchronous cluster
equals \( (N_0/\pi)^2 \), with \( N_0 \) being the number of the synchronous
oscillators. Since both measures, \( g_0(t) \) and \( \tilde{g}_0(t) \), describe the
same property, that is, the degree of spatial synchronization
of the system, we only use \( g_0(t) \) as notation in the following.

As an illustration, consider the two groups of globally
coupled phase oscillators investigated by Abrams et al.\textsuperscript{12} An
exemplary snapshot is depicted in Figure 3(a), where oscilla-
tors \( 1, \ldots, N/2 \) belong to group 1 and oscillators \( N/2 + 1, \ldots, N \)
constitute group 2. Clearly, group 1 is synchronous while the
oscillators in group 2 behave incoherently. In the parameter
region considered, a breathing of the chimera is expressed through an oscillation of the variance of the incoherent cluster
was reported.\textsuperscript{12} The temporal evolution of \( g_0(t) \) is shown
in Figure 3(b). It can be observed that \( g_0(t) \), i.e., the relative
amount of partially synchronized oscillators, evolves periodically and “breathes” over time. Therefore, the temporal evolution of \( g_0(t) \) allows for the discrimination between chimeras with constant and oscillating partial synchronization. We term these stationary and breathing chimeras, respectively. The latter term has been adapted from the literature, since the Kuramoto order parameter \( r \) exhibits the qualitatively same temporal behavior as \( g_0 \).\textsuperscript{12} Note that the two approaches above are independent of the spatial dimension and the number of variables of the different systems. This makes \( g_0(t) \) a versatile tool for the classification of multifaceted data sets such as those obtained from chimera states.

B. A measure for correlation in time

In addition to the measure for the spatial correlation discussed in Section II A, the temporal correlation of the individual oscillators provides valuable information for a distinction between different chimera dynamics as well. Suppose \( X_i \) and \( X_j \) are the real or complex time series of two individual oscillators with \( \mu_i, \mu_j \) and \( \sigma_i, \sigma_j \) their respective means and standard deviations. Then, consider the pairwise correlation coefficients,

\[ \rho_{ij} = \frac{\langle (X_i - \mu_i)(X_j - \mu_j) \rangle}{\sigma_i \sigma_j}, \quad (5) \]

with \( \langle \cdot \rangle \) indicating the temporal mean and \( * \) complex conjugation. Note that \( \rho_{ij} = 1 \) for linearly correlated time series, \( \rho_{ij} = -1 \) for linearly anti-correlated time series and \( |\rho_{ij}| = 1, \angle \rho_{ij} = \pi \) for complex time series with a constant phase shift of \( \pi \). That means, the normalized distribution function \( h \) of

\[ \hat{\mathbf{R}} = \{ |\rho_{ij}| \}, \quad i \neq j \quad (6) \]

is a measure for the correlation in time. For static chimera states, where the coherent cluster is localized at the same position over time, \( h(|\rho| \approx 1) \) is non-zero. In practice, we consider two oscillators as correlated if \( |\rho_{ij}| > 0.99 \). For example, consider the Kuramoto model mentioned above. Again, we map the system onto the complex plane with arbitrary constant amplitude \( A \) for all oscillators. Then, for the chimera state depicted in Figure 4(a), we calculate the correlation matrix \( \mathbf{R} \) and its probability distribution function \( h \). The first row of \( \mathbf{R} \), \( \{ \rho_{0x} \} \), is shown in Figure 4(b). Note that this approach maps the temporally coherent part onto 1, cf. Figure 4(b). The distribution function \( h \) is depicted in Figure 5(a). It exhibits a distinct peak at \( |\rho| = 1 \), indicating that the chimera state is static, i.e., that the majority of oscillators does not change its “group affiliation.” We suggest to term this kind of chimera state a static chimera. The peak at \( |\rho| \approx 0.5 \) arises due to the partial linear correlation between oscillators at \( x \approx 0.5 \) and synchronous oscillators, cf. Figure 4(b). The percentage of the time-correlated oscillators can now be quantified with

\[ h_0 := \sqrt{\int_\gamma h(|\rho|) d|\rho|}, \quad (7) \]
e.g., $h_0 \approx \sqrt{0.08} \approx 0.28$ for the Kuramoto model, see Figure 5(b). Note that $h_0$ does not always reflect the size of the synchronized cluster. This is especially the case when coherent and incoherent regimes are non-static and perform spatial movements over time. Then, $h_0$ is much smaller than $g_0(t)$ and may vanish for large enough time windows. $h_0$ coincides with $g_0$, cf. Figure 5(b), if and only if the chimera is static and no spatial coherence is present in the incoherent cluster.

III. EXAMPLES OF CHIMERA STATES AND THEIR CHARACTERIZATION

As shown in Section II, $g_0(t)$ of the Kuramoto model remains constant in time and, in addition, coincides with $h_0$. This indicates the constant phase relation between the coherent and incoherent part and their spatial stationarity in time. The same qualitative behavior can be observed in many different non-locally coupled dynamical systems, such as in non-locally coupled Stuart-Landau oscillators investigated by Bordyugov et al.\textsuperscript{7} and in chimera states observed by Sethia and Sen in a non-locally coupled version of the complex Ginzburg-Landau equation (CGLE).\textsuperscript{10} A snapshot and the observables $g_0(t)$ and $h_0$ of the latter are depicted in Figures 6(a) and 6(b), respectively. If $h_0$ is larger than 0, independent of the size of the regarded time frame, then one can conclude that the chimera state is stationary in the sense that the incoherent and synchronous patches do not move. According to our definition above, this chimera state is a static chimera. Moreover, the finite values of $g_0(t)$ and $h_0$

![Figure 7](image-url)  
**Figure 7.** (a) Snapshot of the chimera state observed by Omelchenko \textit{et al}. (Ref. 9) and Hagerstrom \textit{et al}., section IV in the supplementary material.\textsuperscript{24} In the right part a magnification of the dynamics in the indicated rectangle is shown. (b) $g_0(t)$ and $h_0$ of the chimera state in (a).

indicate that the desynchronized dynamics are both spatially and temporally incoherent.

An example of a static chimera state not exhibiting temporal incoherence was examined by Omelchenko \textit{et al} in a system of non-locally coupled maps with a period-2 orbit,\textsuperscript{9} and subsequently experimentally realized by Hagerstrom \textit{et al}\.\textsuperscript{15} As depicted in Figure 7(a), the individual realizations are located on two stable branches. As evident from Figure 7(b), for these chimeras $g_0(t)$ is constant and smaller than 1, while $h_0$ equals 1. The value of $g_0(t)$ between 0 and 1 affirms that we are dealing with a chimera state, while the fact that $h_0 = 1$ attests to the absence of any temporal incoherence.

As already mentioned in Section II A, the temporal evolution of $g_0(t)$ can be used to identify different dynamic behaviors of chimera states. Apart from being constant, $g_0(t)$ can oscillate in time for a breathing chimera state, as already shown in Figure 3(b) for the two-groups approximation.\textsuperscript{12} Another example is the so-called type II chimera, which was reported in the CGLE with nonlinear global coupling.\textsuperscript{14} The temporal evolution of the absolute value of the complex amplitude and the observables $g_0(t)$ and $h_0$ are depicted in Figures 8(a) and 8(b), respectively. In Figure 8(b), the oscillatory behavior of $g_0(t)$ is evident, indicating partial synchronization also in the incoherent regime. Note that within the incoherent cluster, there are always homogeneous patches, leading to the offset between $g_0(t)$ and $h_0$.

Besides oscillating in time, the observable $g_0(t)$ can also vary irregularly. Such a behavior can be observed in the so-called type I chimera in the CGLE with linear global coupling.\textsuperscript{18} A representative evolution of the modulus of the complex amplitude $W$ and the corresponding measures $g_0(t)$ and $h_0$ are depicted in Figures 9(a) and 9(b), respectively. Note that $h_0$ is significantly larger than 0, indicating that the
chimera state is static. The irregularity in $g_0(t)$ arises from spatio-temporal intermittency, which appears spontaneously in the turbulent regime, leading to the emergence of patches of oscillators that are synchronous with the coherent region and shrink and disappear with time. Non-stationary chimera states with irregular phase boundaries were also reported by Bordyugov et al.,7 who named this state a turbulent chimera. We adapt this expression for general chimera states with irregular variation of the partial synchronization, $g_0(t)$.

Dynamics resembling the type I chimera in some aspects is the spatio-temporal intermittency as observed in the CGLE.25 A realization of the spatio-temporal intermittency in the one-dimensional CGLE is shown in Figure 10(a). In Figure 10(b), the irregular evolution of $g_0(t)$ is apparent. However, in contrast to the type I chimera discussed above, $g_0(t)$ drops to zero at different points in time. This means that the coherent part, and with it the coexistence between synchrony and incoherence, vanishes completely from time to time. Therefore, spatio-temporal intermittency should not be considered to represent a chimera state.

$h_0$ is also small ($<0.05$), and results from the correlation of neighboring points due to diffusion. Dynamics with reversed roles, which are turbulent patches appearing in an otherwise homogeneous regime, are found in the CGLE with linear17 and non-linear global coupling18 and are called localized turbulence. An example is shown in Figure 11, with a snapshot of the modulus of a two-dimensional simulation in (a) and the temporal evolution of a one-dimensional cut in (b). The corresponding correlation measures $g_0(t)$ and $h_0$, calculated from the two-dimensional spatio-temporal data with system size $L = 200$, are depicted in Figure 12(a). The fluctuating value of $g_0(t)$ suggests that the degree of coherence changes with time. A strong increase of the synchronous part occurs at $t \approx 1350$, indicating a strong non-stationarity. However, calculations with larger system sizes suggest that the variations vanish in the thermodynamic limit $N \to \infty$. An illustration is depicted in Figure 12(b), where $g_0(t)$ was calculated from two-dimensional simulations of systems with $L=2000$.

A characteristic feature of localized turbulence, as compared to all chimera states discussed above, is that the turbulent islands are composed of several incoherent “bubble-like” structures, which move erratically in the spatial domain. Bubbles disappear or pop up through division of existing bubbles. Due to this steady motion of the turbulent islands, the fraction of the coherent time series as measured by $h_0$ is small, and vanishes if the time window is chosen large enough. The same holds for the alternating chimeras observed by Haugland et al.,26 where the turbulent part alternates with the homogeneous regime in time (not shown).

### A. Transient chimeras

So far, we did not consider the long-term stability of the chimera states yet. However, especially in the context of chimera states, defining a stability concept is an important issue.
While various chimera states, as the type I and type II chimeras mentioned above, are the only attractors for a specific parameter region, and as such are stable, many other chimera states including those of the Kuramoto model are long-term transients with infinite transient time in the continuum limit $N \to \infty$. Then, there exist states encompassing coexistence of coherence and incoherence that collapse to the homogeneous state after a finite time even for $N \to \infty$. An example thereof is the so-called amplitude chimera. The space-time realization of such a state is depicted in Figure 13(a). Figure 13(b) shows the evolution of $g_0(t)$. Amplitude chimeras resemble the chimeras found in coupled period-2 maps (cf. Figure 7) insofar as they are composed of two coherent domains with anti-phase behavior that are separated by a spatially incoherent interfacial region. In the latter region, the absolute values of the amplitudes vary erratically in space but each oscillator is strictly periodic with a frequency equal to the frequency of the synchronous regions. The spatial incoherence renders $g_0(t)$ smaller than 1. However, as investigated in detail by Loos et al., and also evident from Figure 13, the chimera-like dynamics are not stable. A transition to full synchronization can be observed, i.e., $g_0(t) = 1$ after a finite time interval. In this case, the lifetime of the chimera state strongly depends on the choice of the initial conditions and asymptotically approaches a constant value in the continuum limit.

We consider it meaningful to discriminate between transient chimeras and chimera states which are attractive in the continuum limit. Therefore, we suggest to introduce a separate class transient chimeras for states with $0 < g_0(t) < 1 \forall t < t_0$ and $g_0(t) = 1 \forall t > t_0$ at some transient time $t_0$.

Another remarkable case that created controversy as to its characterization as a chimera was reported by Falcke and Engel in a globally coupled version of the CO-oxidation model. There, turbulent patches appeared in an otherwise homogeneously oscillating background, similar to the localized turbulence discussed above. But, in contrast to the behavior in the localized turbulence, no turbulent bubbles ever disappear. A one-dimensional simulation is depicted in Figure 14(a), with the corresponding measure $g_0(t)$ plotted in Figure 14(b). There, the incoherent region expands into the synchronously oscillating domains with an approximately constant velocity that is strongly dependent on the diffusion coefficient $D$. This non-stationarity manifests itself in the overall systematically declining behavior of $g_0(t)$. In such a case, a longer simulation time is necessary in order to verify that $g_0(t)$ vanishes after a finite time interval, which was confirmed for the present case. Since it mediates a transition from an unstable to a stable state, it fulfills the above defined criteria for a transient chimera state. We thus classify it accordingly.

B. Experimental observation of chimeras

Chimeras have also been observed in experimental setups. In this section, we apply our approach to experimental data as described by Schöneleber et al. In this system, the thickness of a SiO$_2$ layer on a Si-electrode oscillates due to simultaneous electrochemical oxidation and etching. Changes in the SiO$_2$ thickness are measured via ellipsometric imaging. A snapshot of a measurement is depicted in Figure 15(a), with the color indicating the thickness of the oxide layer. The experimental data was processed using a moving average filter to smooth the data and to remove high-frequency noise. The resulting time series is shown in Figure 15(b) for a one-dimensional cut through the measurement shown in Figure 15(a).
average over the last 10 time frames. The temporal evolution of a one-dimensional cut is shown in Figure 15(b), where the homogeneous oscillation of a small region in an otherwise inhomogeneously oscillating background can be observed. Figure 16(a) shows the pairwise correlation coefficients of the cross-section with a point inside the coherent cluster (here \( y = 80 \)): a strong linear correlation within this cluster and the diminishing correlation with the remaining oscillators is evident. In Figure 16(b), the behavior of \( g_0(t) \) with time and the value of \( h_0 \) are shown. They are remarkably similar to type II dynamics as depicted in Figure 8. Hence, we can conclude that the observed experimental chimera is of the breathing type. The smallness of \( h_0 \) originates from the fact that the coherent cluster is relatively small.

IV. CLASSIFICATION SCHEME

Above, we introduced two correlation measures, \( g_0(t) \) and \( h_0 \), which allow a quantification of coherence and incoherence in dynamical systems. For phase oscillators, the local Kuramoto order parameter already quantifies the degree of incoherence as a function of space and time. In contrast, our global measure \( g_0(t) \) yields information about the total relative sizes of the coherent and incoherent parts of the system, but does not contain information about local properties within the incoherent group. Nevertheless, it exhibits distinct qualitative types of temporal behavior for chimera states with visibly different dynamic features, and thus, like the local order parameter, can be used to discriminate between chimeras, transient chimeras, and other types of dynamics. Its main advantage is its unrestricted applicability, not only to ensembles of phase oscillators but also to any type of dynamical system. Thus, \( g_0(t) \) allows for a simple and straightforward classification of general chimera states.

For \( g_0(t) \) equal to 0 or 1, one of the two phases, the coherent \((g_0(t) = 0)\) or incoherent one \((g_0(t) = 1)\), does not exist. This contradicts the requirement of “coexistence,” and we argue that dynamical states where this occurs should be differentiated from chimera states. This includes spatio-temporal intermittency, the turbulent patterns in the CO model and the amplitude-chimeras shown in Figure 13. Yet, for the latter two, \( 0 < g_0(t) < 1 \) is valid for a long time interval. Therefore, we suggest that these states are categorized as transient chimeras. In the case of intermittency, \( g_0(t) \) fluctuates constantly, thereby attaining a value of 0 after arbitrary periods of time. It is therefore differentiated from chimera states.

Chimera states, i.e., states with \( 0 < g_0(t) < 1 \), can then be classified into three groups:

![FIG. 16. (a) Correlation coefficients for \( y = 80 \) for the one-dimensional cut shown in Fig. 15(b). (b) \( g_0(t) \) and \( h_0 \) for the whole data set.](image)

![FIG. 17. Characterization of chimera states by means of \( g_0(t) \) and \( h_0 \). The different examples of chimera states discussed in this paper are given in italics. In order to distinguish between no chimera and transient chimera, the transient time \( t_0 \) has to be much larger than the characteristic time of the uncoupled dynamics.](image)
(1) Stationary chimeras: Chimera states with constant coherent cluster size $g(t)$

(2) Turbulent chimeras: Chimera states where the temporal evolution of $g(t)$ is irregular

(3) Breathing chimeras: States in which the behavior of $g(t)$ is periodic

Note that there might be some ambiguity in the assignment to these sub-categories, since the boundaries between stationary/turbulent and turbulent/oscillatory are rather fluent.

Based on the temporal correlation measure $h_0$, these groups can be further divided into three subclasses:

(a) Static chimeras, in which the coherent cluster is confined to the same position in space over time. That means, $h_0$ is non-zero and independent of the time window evaluated.

(b) Moving chimeras, where $h_0$ vanishes if the regarded time window is taken sufficiently large.

(c) Time-coherent chimeras, that is chimera states with no temporal incoherence and thus $h_0 = 1$.

These criteria are summarized in a chimera classification scheme shown in Figure 17. The examples discussed in Sections II and III are assigned accordingly in the classification tree.

In conclusion, we have introduced two observables, $g(t)$ and $h_0$, that are a measure for the degree of spatial and temporal coherence, respectively, and allow for a discrimination between different types of chimeras from simulated or experimental spatio-temporal data sets. All examples from literature considered here could be assigned to one of the classes. We verified the generality of the approach with additional examples, such as the FitzHugh-Nagumo and Rössler models.

Note, however, the scheme does not distinguish between single- and multi-headed chimeras. Furthermore, it is likely that future studies will reveal additional phenomena which the method does not account for at the current stage. However, even in this case, the classification scheme should present a useful base skeleton that can be expanded as new discoveries will dictate.

ACKNOWLEDGMENTS

We thank Maximilian Patzauer and Konrad Schönhoffer for providing the experimental data and for fruitful discussions.
